BY

SIR WILLIAM FERGUSSON, BART.

F.R.S.

SERJEANT-SURGEON TO THE QUEEN,

AND PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

FIFTH EDITION.

LONDON:
JOHN CHURCHILL AND SONS, NEW BURLINGTON STREET.
M.DCCC.LXX.
LONDON:
SAVILL, EDWARDS AND CO., PRINTERS, CHANDOS STREET,
COVENT GARDEN.
My dear Wood,

As my immediate successor in the Chair of Surgery in King's College, which I had the honour to occupy for thirty years, I beg, in token of much regard and friendship, to dedicate this edition to you.

Yours very sincerely,

Wm. Fergusson.

To John Wood, Esq.,
King's College, London.
It has been the object throughout the whole of this work to produce a volume of the details of Practical Surgery, which shall, in some degree, meet the wishes and wants of the Student, as well as the Surgeon already engaged in practice. All hypothetical doctrines have been avoided as much as possible, and alluded to only when they have afforded palpable illustration of certain methods of practice. The prevailing custom of interspersing surgical works with Physiology has been dispensed with as much as circumstances would permit, chiefly on the ground that this subject, besides being too comprehensive to be treated in such a manner, forms only a part of that extended education on which a Scientific knowledge of Surgery can alone be based. For the same reasons, too, the sciences of Chemistry, Pharmacy, Materia Medica, and others, which are included in the curriculum of medical study, have scarcely been referred to; not because they are irrelevant to the Practice of Surgery, but because each, in a manner, forms a separate department of that system of instruction which belongs alike to the Physician and the Surgeon, and which every properly qualified medical man must have pursued ere he becomes a recognised practitioner.

In the arrangement and progress of the work it was found that unless such a section as that which has been named "The Elements of Practical Surgery" were given, there would be a series of repetitions elsewhere, which could not have been avoided. The section in question is, like the others, devoted almost exclusively to practical details, and the Author wishes that it shall be taken in this light alone by the Student and all who may look into these pages,—for, strictly speaking, the true elements of Practical Surgery are to be found chiefly in a complete system of education.

Each subject has been treated according to the Author's estimate of its utility and importance,—an estimate founded partly on his own education, partly on the writings of others, but more particularly on
his experience among pupils and brother practitioners. He has generally assumed that his personal opportunities have been such as to entitle him, on all fitting occasions, to illustrate his precepts by his own practice, although he must here express a hope, that in the following pages he will not be found deficient in respect for the opinions of others.

The limited extent of the volume has necessarily prevented notice being taken of various subjects of special interest to the Practical Surgeon, and also of those historical details for which some might wish. While the Author cannot but regret the omissions, he trusts that, in some degree, they will be compensated for in other respects, and that few of his readers will be without that admirable emporium of surgical lore, "Cooper's Surgical Dictionary," or the "Cyclopædia of Practical Surgery." The English edition of "Chelius' Surgery," by Mr. South, the works of Erichsen, Pirrie, Spence, and notably the "System of Surgery" edited by Mr. T. Holmes, will amply supply all that can be reasonably desired on such topics.

The pen has been freely struck through many portions of the last edition, and considerable additions have been made to the present, both in letter-press and illustrations; but there will yet appear much wanting towards perfection, especially in the estimation of those who look for something pertaining to all surgery under the title of "System."

The Author feels much indebted to many friends and former pupils for aid in carrying out his task, especially to Mr. Henry Smith, Mr. Teale of Leeds, Mr. Royes Bell, and Mr. Francis Mason, to whom he tenders his warmest thanks.

With many imperfections of which he is himself conscious, and probably many more which may have been overlooked, he ventures to hope, with regard to this, the Fifth Edition, that the good, if any, may be put against the bad, and that the result will be, that he has contributed, in some measure, to the advancement of a profession to which he has been devotedly attached for more than forty years.

16, George Street, Hanover Square, September, 1870.

A SYSTEM
OF
PRACTICAL SURGERY.

PART I.
INTRODUCTION.

THE ELEMENTS OF PRACTICAL SURGERY.

CHAPTER I.
INSTRUMENTS, INCISIONS, DISSECTIONS AND OPERATIONS.

A work on practical surgery cannot be more appropriately commenced than with some general observations on the manner of making those dissections, which are necessary for the display of surgical anatomy; and some general remarks on operations and surgical instruments and apparatus, may be advantageously introduced at the same time.

For the investigation of surgical anatomy, a subject should be selected on which disease has not caused too great emaciation; nor, on the other hand, should the textures be obscured by an over-abundance of fat. In the latter case the parts cannot be displayed so clearly as may be wished; and in the former, although they can be most distinctly made out, no very correct notion can be formed as to the appearance of the same structures, when exposed in the living body, as operations, being generally done on those of an average bulk of development, are seldom required or performed on individuals who are either much emaciated by disease, or overloaded with fat.

In all instances, dissections and operations on the subject should, if possible, be performed with instruments similar in every respect to those intended to be used on the living body. The scalpel is the cutting instrument in most general use, and one with a blade of this size and shape (fig. 1) will be found to answer most purposes to which
the instrument is applicable. The handle and blade together should be about six inches in length; the former of ebony, and the latter of steel so finely tempered, that its edge cannot be readily turned or broken. Ebony should be preferred to ivory for the handle, as it is less likely to slip in the fingers when covered with blood or moisture of any kind, and its surface should be smooth throughout its whole extent. The blade and handle should be firmly joined, and the rivet-pins should be made of such a material as will not readily corrode or rust. German silver is a good metal for the purpose. A stronger and more bulky instrument is preferred by some, and others, again, occasionally select a smaller one; some have the cutting edge more convex, others less so; a few prefer a double edge, and some choose the point on a level with the back of the blade. Each anatomist and surgeon has a taste of his own in these matters, and it is of no great moment which shape or size is selected, provided he who wields the instrument has the skill and dexterity requisite for its proper application. With such an instrument as is here recommended, I have performed most of the capital operations of surgery,—from those requiring the most careful dissection, to the most rude that can be imagined; from cutting on large arteries, for hernia, for lithotomy, for the removal of tumours from important parts, to the extirpation of large growths where extensive and rapid incisions have been resorted to; indeed, in case of necessity, an instrument of this kind might even be used in amputation of either extremity; but in proper time I shall describe others which are better adapted for the peculiarities of each operation.

The scalpel should be held between the thumb and fingers, by the thickest part of the handle, with such a degree of firmness only, that its weight may still be felt. Either of these positions here represented may be resorted to, although the first (fig. 2) is usually deemed best

Fig. 2.

for general purposes. The little finger may be placed on the neighbourhood parts, so as to support the hand, and assist in steadying it; but when extensive incisions are required, the instrument should be laid on with the hand unsupported. The other method, exhibited in fig. 3, requires great steadiness naturally, but with practice, much ease, elegance, and dexterity may be displayed when the knife is thus held, and even the most minute dissections may be effected with the hand and scalpel in this attitude.

Many operations are performed with the bistoury, and it will be ad-
vantageous to practise dissections with it, as well as with the scalpel, so that it may be handled without awkwardness on the living body.

Fig. 3.

A blade of the shape represented in figure 4, about three or four inches in length, fixed in a handle similar to that of the scalpel, or in such a one that the blade can shut like a pocket-knife, may be used on these occasions. The instrument may be held in the same manner as the scalpel; it is awkward, however, to do so in the manner exhibited in figure 2, in consequence of the fingers being so near the point; and that here shown (fig. 4), perhaps, combines more elegance, freedom, and firmness of, movement than any other. Whatever attitude is chosen at first, it is necessary, with appropriate movements of the fingers and wrist, so to change the position of the hand during the incisions, that the cutting edge of the instrument may be drawn or pushed towards the operator, or from him, at will. There are different kinds of bistouries which I shall refer to afterwards, and both these and the scalpel require to be held in particular attitudes, which will be most advantageously explained and exhibited, in describing the manner of performing the various operations, in which such instruments and positions are of consequence.

In minute dissections, scissors (fig. 5) will be found of service, and as they are frequently required in the practice of surgery, the hand should be habituated to their use. The shape indicated in the sketch is such as I prefer, and the length should be about five inches and a fourth. For ordinary surgical purposes the shapes exhibited at p. 35 are more suitable. It will be afterwards found that I seldom recommend scissors for any operation when the knife may be applicable. But they are useful in a variety of ways in almost every occasion of the kind, and in cutting ligatures, stitches, straps, bandages, &c., they are
indispensable. Occasionally, however, these instruments are best adapted for certain operations, and I shall therefore refer to them again at fitting opportunities.

In dissections or operations requiring cautious cutting, the knife should be drawn or pushed lightly and steadily along the surface, and with such force that the textures, as they are divided, shall fall gently to each side. The pressure must be regulated by a variety of circumstances, such as the depth to which it is wished to carry the incision, the nature of the texture to be cut, and the proximity of important parts. Sometimes a bold and free division is required through a considerable thickness of parts, when a sawing motion of the hand is of advantage; at other times slight movements with the point of the blade will suffice. In general, if the edge be sufficiently fine, and dexterously moved along, the textures will be readily separated without much apparent rudeness, and without the appearance of scratching, as if a pin was used instead of a sharp-edged weapon.

It may be deemed supererogatory to state, that the knife should, with few exceptions, be held in the right hand. It is proper to mention this, however, as some, on the often-quoted authority of Celsus, contend that the surgeon should be as dexterous with the left hand as with the right; affirming, that he should do all the operations of surgery as well with the one as with the other. To me it has always appeared that this may not have been the meaning of that distinguished authority; nor do I think it at all requisite on the part of the surgeon that he should use the knife as dexterously with the left hand as with the right. It will be of advantage to dissect occasionally with the left hand; but there are few who will attain the same command over it as over the opposite one. From infancy we apply each hand to special purposes; the left hand has its peculiar duties to perform whilst the other is engaged,—it may be said to be the servant of the right; and on the part of the surgeon this seems to me all that is necessary; for it is surely as absurd to expect ambi-dexterity with him, as it would be to expect, or recommend it, with the painter, sculptor, or common mechanic. I have never yet seen a surgeon who possessed equal power and grace in either hand, nor do I consider that the efficient practice of this art requires that kind of dexterity possessed by the juggler, who tosses his daggers, and catches them again as they twirl through the air, as freely with the one hand as with the other, and with whom the abilities of each are, of necessity, nearly alike.
In minute dissections the forceps is in general use, although, with a little practice, great nicety and firmness may be acquired with the thumb and finger used as a substitute. In all instances where the thumb and fore-finger of the left hand can be used to put the parts, about to be divided, on the stretch, they should be preferred to the forceps. For ordinary purposes, an instrument similar to that represented in this sketch (fig. 6), will be found very useful; it should be between four and five inches in length, and where the free ends of the blades meet, the surfaces should be grooved obliquely, so as to fit accurately into each other. The points should be rounded and of considerable breadth; and whilst capable, from being thus shaped and nicely fitted, of seizing the most minute objects, they may, when required, grasp others of greater size, and secure them firmly. This construction of point is, in my opinion, greatly to be preferred to the slender and dangerously sharp extremity, which I see in many of the instruments that come under my frequent notice. The spring in the blades should not be very strong, as the hand, in using them, would speedily get fatigued, nor should it be weak, as the points will not separate with proper freedom. In dissection this instrument is held between the thumb and fore and middle finger of the left hand; but it is often used in the right, in securing arteries during cutting operations, from the greater facility in manipulating with this hand.

A variety of hooks, sharp or blunt at the point, may be used in place of forceps, but the latter is generally preferred. In dissections, the chain hooks represented in fig. 7 will often be found of service; but if the parts can be put on the stretch with the thumb and fingers, or between the forceps and little finger of the left hand (the instrument being held between the thumb and two fingers), their use had better be dispensed with, as the fingers often get scratched with their points. Instead of these a hook fixed in a handle like that of a scalpel, as here exhibited (fig. 8), may be had recourse to; its point, it will be observed, is sharp, and it is often of advantage to have it so, whilst on other occasions a blunt point is to be preferred, such as in fig. 9, and either of them may be single, as they are here represented, or double, as is seen in fig. 10. The hooks set in handles are mostly used during operations, and then they are held by assistants; they are of service in keeping parts out of the way of the
surgeon, and very useful in many operations. They take up less room than fingers on the edge of a wound, and generally hold the parts more securely. Slips of copper bent at the points, or flat pieces of wood, are sometimes used for similar purposes, as, for example, in holding asunder the edges of the wounds which are required for ligature of the large arteries at the root of the neck, or in the pelvis.

When sufficient familiarity with the different parts of the body has been attained, by frequent dissections, the operations of surgery should then be performed on other subjects. The cutting instruments, above referred to, are now in general to be used in a more free and bold style than in ordinary dissection, and more extensive movements are required in the hand and arm, though occasionally the operator has to proceed with as much caution as if making the most minute dissection on the dead subject. There cannot be a greater mistake in a young surgeon’s education, than to commence the performance of operations before he has acquired a thorough knowledge of anatomy. If he enters into practice without such knowledge, he can neither operate with safety to his patient nor satisfaction to himself; all must be hap-hazard; whilst on the other hand, in prosecuting his dissections, he takes the surest way of acquiring that dexterity in the use of his hands and instruments, which will be of infinite service to him afterwards in the ordinary performance of his professional avocations. Here I do not so much allude to the performance of capital operations, as to the more common manipulations required in bloodletting, ban-
daging, dressing sores, opening abscesses, and the numerous little manual proceedings which constitute the routine of surgical practice, which, though seldom named as "operations," should be deemed as characteristic of good practical surgery, as the dexterous removal of a limb, or the rapid and successful extraction of a stone from the bladder.

In the performance of many operations, as well as in certain dissections, a saw is necessary, and as it is difficult to use it in a workman-like manner, it will be well to practise with it on wood or bones, the latter being preferable when they can be procured in sufficient abundance; for it is not by sawing through the bones of one or two extremities merely that a masterly use of this instrument can be acquired. The common dove-tail saw is that best fitted for general purposes. One with the blade about nine inches long and two and a half deep, exclusive of the back, will serve on almost all occasions on which a saw is required. I prefer a handle, such as is here exhibited

![Fig. 11](image)

(fig. 11) on a diminished scale, similar in shape to that used by the cabinet-maker, made of ebony, and of such a size that, whilst held in the palm, it can be firmly grasped by three fingers, the forefinger and thumb being placed parallel with its upper margin, to aid in keeping it steady. The blade should be sufficiently firm not to bend on the application of moderate force; the teeth should be about this size (fig. 12), and well set out, so as to make such a breadth of groove as will allow the blade to move in it with facility. In using this instrument, it should be held in the right hand, as above directed, the part of the serrated margin nearest the hand should be placed on the bone, and by drawing it steadily backwards a slight groove will be made; it should then be pushed forwards, and, by repetition of such movements, extending on each occasion nearly the length of the blade, with a moderate degree of force and rapidity, a bone, the femur, for example, may be cut through in a few seconds. In many operations the full sweeps here indicated cannot be effected, and a much shorter blade will suffice; indeed, there are great varieties of saws, some of which I shall depict afterwards, as being better adapted for particular operations, and I shall then also describe the manner in which these as well as that now alluded to, are to be applied and used for each special purpose.
The cutting forceps (fig. 13) may be substituted with great advantage for the removal of portions of bones, when the saw cannot be readily applied. There is but little skill required in using it, strength of hand being the chief requisite. The cutting edges are brought together by compressing the handles betwixt the palm and fingers. The pressure should be forcible and steady, and on no account should there be any shaking or twisting of the handles. In partial amputation of the fingers or toes, hand or foot, it may on all occasions be used in preference to the saw. I have even divided the femur with it on the young subject. The saw, however, ought to be preferred for the large bones in amputations of the extremities.

For the removal of diseased or dead portions of bone, when the neighbouring healthy bone requires to be cut, it may, unless the tissue be exceedingly hard, entirely supersede the common saw, or any other which the surgeon might be disposed to select. Indeed, though this is a somewhat ancient surgical instrument (for it was figured by Seulietus more than two hundred years ago), and though it had become in a manner obsolete till within these forty years, I know of no single instrument whose re-introduction to practice in modern times has conferred a greater boon on the operating surgeon; and for this we are solely indebted to Mr. Liston, whose example in using it has been most extensively followed by a large proportion of the present race of operating surgeons.

The usual length of the instrument is from eight to nine inches; but various sizes may be used, according to circumstances. The parts behind the joint should be very strong, so that they shall neither bend nor break with the strength of the surgeon's hand; the cutting edges should be sharp, and come exactly in contact when the handles are shut; and they should be finely tempered also, so as not to be readily turned or broken. When used, the blades open, and are made to grasp the object to be divided, with the flat surface, nearest the healthy parts; the handles should be squeezed towards each other, when, if sufficient force be exerted, the blades will meet, the parts will separate, and the cut surface will look as level as if made with a saw. In a hard bone, such as the lower jaw, or in the tibia when it is necessary to remove a portion of the hard part of the shaft, as in compound fractures, I believe this instrument breaks the textures at the part where it is applied; in softer bones, beside cutting, it partly bruises, and some theorists have objected to its use from the latter circumstance; but on no occasion, so far as I have observed, has this instrument produced more serious consequences on the remaining portion of bone, than the saw might have done, had it been used instead.

Besides the shape of cutting forceps represented on the sketch on
the preceding page, I have been for many years in the habit of using others more conveniently adapted for particular purposes; sometimes I have found that when the blades were curved in this manner (fig. 14) at the point I could effect with them what I could not with the straight ones, and in other instances I have had reason to be much satisfied with the bend exhibited in figure 15. But now I seldom use any other kind than that represented by figure 16, which I prefer to the others on almost every occasion. There are other shapes, too, nearly all of them being derived from the same "Armamentarium," but these (especially 14 and 16) I have found most generally useful in the ordinary operations on bones.

The gouge (fig. 17) is an instrument which has been in a great measure overlooked by the modern surgeon; but I cannot here omit giving it a full measure of praise. It was used by the Moreaus in their operations on carious joints, and has been recommended by various authorities; yet until recent years it has seldom been seen in the surgeon's hands. In operations for necrosis and caries I deem it indispensable, more particularly for the latter; and the amount of good which I have seen accrue from its use in my own practice, leads me to give it the strongest approbation as a most useful surgical instrument. Cases will be referred to in after parts of this work, when its efficacy in operations for caries of the tarsal bones, of the shaft of the tibia, and of the articular surfaces of several of the large bones, will be fully exemplified. The instrument which I generally use is about four or five inches long, including handle; the blade is about half an inch broad, and sharpened at the point like a turner's gouge. Both handle and blade are short, to enable me to rest a finger on the surface near where the instrument is applied, and so prevent any sudden plunge, such as might
happen were it of greater length. The round handle is kept in the palm, whilst the point of the fore-finger directs the scooping movements.

Perhaps there is no department of modern surgery so characteristic of improvement as that connected with the removal of dead or diseased portions of bone. Even after the saw or forceps has been used to perfection, the isolated part may not be easily taken away. If the fingers or common forceps (fig. 6) will not suffice for this, then such an instrument as is depicted in fig. 18 may be very useful. This

**Fig. 18.**

will be recognised by the seniors of the present race of surgeons, as the usual accompaniment of the ordinary pocket dressing-case. In modern times such a case is rarely made so comprehensive in its contents, and this instrument is generally laid aside for special services, although it is often yet used for removing soiled dressings or other purposes, for which the fingers or common dissecting forceps are generally applied. In my opinion the common forceps will do all that may be required of them, as regards dressing a sore or wound, but when it is necessary to dip deep into a narrow space these blades may be of service, especially in removing objects which are somewhat firmly fixed. This instrument is about six inches in length, with blades in proportion, but when some force is required for the removal of pieces of bone, if it seems slender, I use one of greater strength, of nearly similar shape and construction. In certain instances the

**Fig. 19.**

elevator (fig. 19), which figured in the old trepanning cases, is of service in loosening pieces of necrosed bone, and when tumours are to be removed from the osseous structure as in those in the maxilla, especially in the upper jaw, a forceps constructed as is here displayed (fig. 20), six or eight inches long, will be found of great utility. The experience of many years has led me to form a very favourable
opinion of this instrument, which is now familiarly known as the "lion forceps."

All of these instruments will be more or less useful in dissections and operations on the dead body; but there are various implements and apparatus in constant service in similar proceedings on the living body, which are but rarely used on the subject, with which, nevertheless, the young surgeon requires to become acquainted, and which, I think, may, in a work of this kind, be advantageously referred to at the present time.

The probe, which is represented in fig. 21, of its ordinary shape but slightly diminished in size, being usually about five inches in length, is a simple instrument of great service in the practice of surgery. With it the course of deep wounds and sinuses, the presence of foreign bodies, the condition of bones, and a variety of important knowledge can be ascertained: it is of use in many operations; and though the finger is a preferable probe, when its presence is admissible, the metal rod is altogether so serviceable, that the surgeon cannot possibly dispense with its use. It ought to be made of pure silver, so that it will not readily break on being bent: one extremity (the point) is rounded off, and a little larger than the body, the other is generally made with a slit, or eye, or both, through which a thread may be passed, when it is wished to employ the probe for the purpose of drawing a seton through a sinus, passing a ligature under an artery, or for other objects, as shall be more particularly stated afterwards. Other metals are occasionally substituted for silver, and other shapes, sizes, and lengths may be required to track a sinus or wound, or to detect a deep-seated foreign substance. The different sorts of metal bougies for the treatment of strictures, the sound or searcher, which is used to detect a stone in the bladder, are modifications of the probe adapted to the peculiar circumstances of each case; but for ordinary purposes, that now referred to is best adapted for the surgeon's pocket-set of instruments.

A director (fig. 22) is sometimes of use, partly as a probe, and partly to guide a cutting instrument in a desired course. It may very generally be dispensed with, as the finger is much to be preferred even in cases where this instrument is by some considered abso-
Instruments, Incisions.

Iutely necessary, as, for example, in cutting the stricture in hernia, on which occasion the finger is the best and safest guide for the bistoury. I have known a surgeon push a director into the gut in this operation, and thus inflict an injury by using it, which it was his object to avoid with the point of the bistoury. There are instances, however, where it will be highly proper to employ this instrument; and on many occasions it will be found serviceable, in permitting a tolerably free escape of matter through its groove, when it has been thought advisable to open an abscess by a puncture; indeed, some have recommended an instrument of a similar construction with a sharp point, called an "exploring needle," to be thrust into swellings of doubtful nature, so as to allow of blood or matter, if either be present, to flow along the groove. On such occasions, I am in the habit of passing a bistoury into the seat of disease, and by gently turning it half round on its long axis, an opening is made sufficient to permit the exit of a few drops of blood or matter; or, should there be any apparent obstruction, I then pass the common director along the flat surface of the blade, which is next withdrawn, whilst the matter, if any be present, is evacuated through the groove. This instrument is generally made of silver, of the shape and appearance here exhibited, and between four and five inches in length. The handle may either be flat, of a triangular shape, or in the resemblance of a small oblong spoon, like that in the sketch. Various shapes and sizes of directors have been recommended, but for ordinary use I give the preference to such as is shown in the cut. Among those for special purposes, the staff for conducting cutting instruments into the bladder in lithotomy is one of the most remarkable, and due notice will be taken of it in a future part of this volume.

It would be impossible, or, at all events, a useless proceeding, to lay down any set of rules, to which the dissector or surgeon is to give a strict adherence, in practising dissections and operations on the dead or living body. I need not undertake to describe all that may be done on such occasions, but shall now, as in the after parts of this work, content myself with stating what I consider the best methods of procedure, and from time to time referring to such modifications and circumstances as may appear to me most worthy of being noticed. These remarks are, for the purpose of this introduction, very apposite to the subject of incisions, about which so many different directions have been given: indeed, it is no trifling task to study the various lines of incisions, and the different positions for holding the knife whilst making them, which have been described by some authors. To the practised dissector, who of necessity must be familiar with anatomy, such directions are of little service; the different movements of the hand and knife, and the different incisions, are done by him instinctively, as it were; and they are in some respects still less serviceable
to him who is ignorant of anatomy. It is not merely by holding a knife in a certain position, or making an incision of a definite length or form on the surface of the body, that an operation is to be performed; unless a person has a competent familiarity with the structures under the surface, he will do well not to interfere with cutting operations: and I cannot avoid stating here my decided aversion to the method of teaching how to find certain parts,—arteries, for example,—by drawing lines on the surface of the body. With few exceptions, the system is a bad one; for no sooner is an incision made than the line is in a manner lost, and the incision itself may inadvertently be drawn to one side or the other, by the surgeon or by an assistant, so as to be completely off the parts over which it was originally made. Undoubtedly a knowledge of the appearance of textures is of infinitely more value to the operator; and he who can distinguish each by the touch and sight (which can be properly done by him only who has had a previous course of dissections), may be satisfied that he is possessed of that legitimate knowledge which alone ought to embolden him to operate on the living body.

Notwithstanding these observations, I deem it necessary, in a work of this kind, to make a few general remarks on the incisions that are in most frequent use; and also, as I shall do in the progress of the work, to describe those most approved for each operation.

The simple incision (fig. 23), consisting of a straight line, is the one in most common use, and ought on all occasions to be preferred when circumstances will permit, as there is not only less injury done to the parts than by any other, but, in addition, the scar left is less observable. It is more readily made, too, than most others, and its edges can be more accurately brought together.

To effect this incision, the point of the scalpel, or bistoury, held as shown on some of the early pages, should be thrust into the skin at a right angle with the surface; the wrist should then be depressed, and the edge inclined upon the skin; when, after a requisite length of division has been made, the wrist should be elevated, and the instrument, ere it is withdrawn, should again be held nearly at the same angle as when introduced. In this way no "tail," as it is technically called, is left in the incision, or, in other words, there is no scratch made on the surface at the beginning and end of the wound (which merely causes pain to the patient, without being of any advantage in the operation), but a fair cut is effected through the skin, which is fully available for the purpose of reaching the subjacent parts, in proportion to its extent, which latter may vary from the smallest imaginable length to twelve inches or more.

Occasionally, such a wound may be advantageously made by pinching up the skin between the thumb and fore and middle finger of the left hand, then thrusting the knife through both layers at once, and cutting outwards: indeed, when the skin is very loose, this is perhaps the best manoeuvre;—as in the removal of small tumours, or the operation for crural hernia, when the integuments have not become inflamed, or firmly adherent to the parts underneath.
The semilunar incision (fig. 24) is in almost as frequent use as the one above described. It is made by carrying the knife in a lunated direction, as shown in the figure, with similar movements of the wrist, and the same care that the whole thinness of the skin is divided,—the convexity being in any direction which may be deemed best.

When a large extent of the subjacent parts must be exposed, a crucial incision (fig. 25) may be made, by which four portions or flaps of skin may be marked out; or wounds may be devised after the forms of different letters, such as figs. 26, 27, 28, and 29, with the points at the side, uppermost, or in any other convenient place, whereby one flap or more can be shaped out, elevated by dissection, and replaced after the operation is accomplished. These, it will be perceived, are merely simple incisions meeting each other at certain angles.

When it is necessary to remove a portion of integument, as in the extirpation of a diseased mamma, or large tumour, an ellipsis (fig. 30) may be described, by two semilunar incisions, and the parts within the figure removed with the disease. Either of the figures here exhibited may be selected, in accordance with the condition of the skin, and shape of the disease. The cut edges in such cases when placed together form a single line unless a very large portion of skin has been taken away, when probably they cannot be brought into apposition.

There are various modifications of these incisions, which are had recourse to in different operations, as will be afterwards shown; and, from time to time, the surgeon meets with diseases requiring operation, where it is necessary to set aside all general rules, and to shape his incisions in such a way as he judges best fitted to the peculiarities of each case.

As a preliminary step to dissection, the arteries should be filled with a coarse injection of tallow and vermilion, to which has been added a small proportion of carbonate of magnesia. This composition runs sufficiently minute to fill all the vessels of much surgical importance, and keeps well in a dried preparation, should it be thought desirable.
to preserve any of the parts in this manner after the vessels have been dissected: but if the dissector be already a little familiar with the parts, they will appear more as they are met with in the living body, if the arteries are not thus distended, and the veins being usually filled with dark blood, there never can be much difficulty in detecting them.

The body should be placed on a firm table, of a convenient height, and in a good light. Before using the knife, the contour of each part should be carefully studied: the prominences of bone and muscle should be looked at and fingered, and each joint should be examined, and put through its movements. These matters are too generally neglected in the dissecting-rooms; but I know of no exercise, or minor part of education, if it may be so called, which will be more useful to the young surgeon, in enabling him to detect distortion, whether from disease or accident. Both eyes and fingers may be advantageously exercised on these occasions: with the former we can detect the most conspicuous deviations from nature; but, to make assurance "doubly sure," we in general use the latter also; indeed, in all instances, where accurate examination is requisite, we must use the fingers, and by touch we can often acquire a knowledge of important circumstances, of which we might otherwise be ignorant: we should so use both in the practice of surgery, as to be able to make out the cause of ophthalmia to be an eyelash in contact with the conjunctiva, or the symptoms of ileus to be occasioned by the presence of a small hernial tumour,—too minute to be discerned by the eye, but sufficiently large to be detected with the fingers. Mistakes occasionally happen on these points, and I have known them under both circumstances. It is notorious that a common dislocation of the shoulder-joint has often been detected by a glance or touch by one individual, when it had not been discovered by another who had previously examined the case, but who had been devoid of the tactus eruditus, which is considered so essential to the efficient practice of surgery, and to the acquisition of which a due attention to the above hints will in no small degree contribute.

It will also be well, before commencing, to have made some arrangements as to the chief objects to be attended to in the dissection. A previous knowledge of descriptive anatomy, and what the dissector may already know of surgery, will enable him to arrange some convenient plan: a work on anatomy or surgery may be consulted, and it will be of consequence that the dissector should take the best manner of displaying each part to the greatest advantage for surgical purposes.

The dissection may now be commenced, and pursued in accordance with the object in view. It is a good general rule, in prosecuting surgical anatomy, to cut away as few textures as possible, and to displace no structure until its relations to the neighbouring organs have been fully examined. In order to examine deep-seated parts, it is necessary to lay aside, or remove, those that lie over them; but it should never be forgotten, that removing, or even turning them aside to any great extent, cannot be done on the living body; and the more, therefore, that a person accustoms himself to look at deep-seated
textures with the surrounding parts in as near proximity as circumstances will permit, so much the more readily will the same individual expose such textures, should it be necessary to reach them, on the living body.

It will be of consequence to become familiar with many deep-seated tissues by touch as well as by sight, and the fore-finger, of the left hand in particular, should be employed on these occasions. In lithotomy, for example, though the surgeon ought to be familiar by sight with all the parts concerned in the operation, the touch is of as much consequence to him as the sight: more so, I should say, as all the most difficult steps are done, where and when the eyes are of little or no avail. The portion of the body about to be dissected should be placed in the most convenient attitude; each texture about to be cut should be put on the stretch, with the fingers and thumb of the left hand, or with the forceps and hooks, as already described at pp. 5, 6, and 7. Occasionally, the assistance of a friend will be of service; but, undoubtedly, the more the dissector trusts to his own resources, the better will it be for himself; and, with practice, the ring and little finger of each hand can be used to stretch the parts, even when the scalpel and forceps are both in use.

It is well known that much of the dissector's skill may be exhibited by attention to these matters, and an equal extent of arrangement and design is of the utmost consequence to the practical surgeon. Before commencing any operation, its various steps should be carefully thought over, and all reasonable contingencies provided for; some will occasionally occur which no experience or foresight could have anticipated; but no such negligence as the formation of the flaps in a capital amputation, without a saw being in the apartment, wherewith to divide the bone, should ever occur. I have seen such a dilemma, when the surgeon, who had trusted to his assistant to have all the requisite instruments at hand, had to wait till a saw was procured; fortunately, in this instance, the saw was in a contiguous apartment; but Sir Anthony Carlisle used to refer to a similar oversight, when the instrument was many miles off. If the surgeon does trust to an assistant to have all things properly prepared, as he may on certain occasions, he ought still to satisfy himself before commencing an important operation, that nothing is wanting which may be of service. Undoubtedly the responsibility rests with him; and in practising on the dead body, these preliminaries, for the sake of rendering the lesson more complete, should all be as carefully attended to, as if the proceedings were about to be done on the living. The positions of both patient and surgeon are of much moment also; occasionally it may be necessary to change both; but there should be no excuse for a surgeon, who, after forming the first flap in amputation of the thigh, only then discovers that he is on the wrong side of the patient, and, in order to complete the operation, has to walk round to the place where he ought to have been at the commencement. I have seen an occurrence of this kind, and, as a teacher, I must say, that although such untoward events may not be of serious consequence to the patient,
assuredly they reflect little credit on the surgeon, or on the art which he professes.

On the dead subject it is not necessary to provide all that may be required on the living; but, for the sake of illustration, I shall suppose a case occurring in practice;—in which event, then, to make sure that all the requisite apparatus for an operation is provided, the best plan is to lay everything in order on a small table or tray, which can be placed near the surgeon; as, for example, in a capital amputation, they may be placed thus: a tourniquet, if one is deemed necessary, to command the circulation; a knife, to cut the soft parts; saw to divide the bones; cutting forceps to remove, if needful, spiculae of bone; forceps and tenaculum to lay hold of the arteries requiring to be tied; ligatures to apply to these vessels; needles with thread to stitch the wound—straps of adhesive plaster, lint, and bandages, to dress it; sponges with water, cold and hot, to wipe away the blood; and such other apparatus as, from the circumstances of the case, the surgeon may deem requisite: moreover, no capital operation should ever be commenced without some cordial being ready, in case the patient should grow faint. Wine is generally provided on such occasions; but it may be well in some instances to have stronger stimulants at hand, as brandy, whiskey or a pungent preparation of ammonia. The quantity of wine which a patient will take during the performance of a severe and protracted operation is often remarkable; and this should be kept in view when a formidable proceeding is contemplated. During amputation in the thigh, an accident occurred with the tourniquet, and the patient, already much exhausted by disease, grew faint from the sudden loss of blood, as well as from the shock of the operation; his pulse was gone at the wrists, and scarcely to be felt in the arms; his face was pale, cold, and clammy, and his eyes had the glassy stare of speedy dissolution; yet he was roused from this alarming state by the rapid exhibition of wine, having in the course of a few minutes swallowed fourteen ounces of that fluid.

Besides these arrangements, some previous understanding ought to exist between the surgeon and assistants, who must, of necessity, be present at a capital operation. Supposing the operation is an amputation, one must be placed to compress the main artery, if a tourniquet is not used; another to retract the flaps; a third to hand the instruments or take them from the surgeon; a fourth to take charge of the sponges and warm water; there may be others to assist in securing the patient during his struggles, and of course if a large portion of a limb is to be removed, an assistant must be instructed to keep it steady during the operation. When the surgeon has it in his power to provide a number of assistants, he ought always to do so; occasionally, however, he must economize his forces, which he will have little difficulty in doing, if he be possessed of that natural or acquired coolness, aptitude in emergencies, and knowledge of what he is about, which are almost equally essential to the welfare of his patient and his own comfort.

The agencies referred to in the ensuing chapter modify in certain respects some of the observations in the two last paragraphs.
CHAPTER II.

ANÆSTHESIA—ETHER—CHLOROFORM—AMYLINE—METHYLENE—

NITROUS OXIDE GAS.

Since the early editions of this work were published, a vast and important change has come over the department of operative surgery. The discovery of anaesthesia, or the means of causing insensibility to pain during the performance of operations, has been made in the interval, and now, instead of wild cries or stifled screams and groans, coming from the patient under the surgeon's instruments, he may be made to lie as quietly as if in a calm sleep, and possibly during the application of the knife he may be mentally engaged in the most pleasing associations of thought, or singing or humming by snatches some favourite air. It is perhaps not saying too much when this discovery is characterized as the greatest, in most respects, which has been made in the province of surgery. Much of the horror, and, doubtless, some of the hazard connected with operations have now been set aside, and a patient can contemplate such means of eure with a calmness and seeming fortitude which even the bravest or most stoical could not maintain in former times. For this valuable discovery we are indebted to some of our Transatlantic brethren. The agent first used to produce this remarkable effect was sulphuric ether. There have been disputes as to the amount of merit due to various parties who, in one way or other, contributed to the development of our knowledge of this wonderful agency. It seems generally understood that Dr. Charles Jackson, Professor of Chemistry, at Boston, suggested the use of sulphuric ether as an anaesthetic to Dr. W. Morton, dentist, of the same city, who used it with happy effect in tooth-drawing early in October, 1846, and it is beyond all doubt that this gentleman was the first to prove that such an agent could be used safely and with perfect effect. The suggestion of Sir Humphry Davy, in 1800, regarding the use of nitrous oxide for this purpose; the trial of the same agent by Dr. Horace Wells in modern times; the recommendation of the inhalation of ether by Dr. Richard Pearson, of Birmingham, in 1795, for pulmonary affections, and the subsequent observations, to a similar effect, by Nysten, in 1815; the occasional use of the vapour of ether by various individuals for the purpose of alleviating bodily or mental anguish, had little, if any, influence in bringing forth this grand discovery; and had it not been for the experimentum crucis of Dr. Morton, we might yet have been in ignorance of the means of rendering the performance of operations painless. On the 16th of October, 1846, Dr. J. C. Warren, of Boston (a name previously renowned in the annals of surgery), performed the first surgical operation, excepting those by Dr. Morton on the teeth, in the Massachusetts General Hospital, under this agency. The case was one of tumour in the neck. The next day
Dr. Hayward, of the same city, removed a fatty tumour, and on the
7th of November following, the same gentleman performed amputation
of the thigh, and Dr. Warren removed a portion of the lower jaw.
The news of the discovery was soon wafted across the Atlantic. On the
17th of December of the same year, Dr. Booth, of Gower-street, London,
received information on the subject; on the 19th, Mr. Robinson, the
dentist, extracted a tooth under the influence of the vapour of ether,
and two days after Mr. Liston, ever in the van in true surgery, showed
to the as yet sceptical beholders, that the formidable operation of
amputation of the thigh might be performed without the consciousness
of the patient. By the end of the year, or within a few weeks there-
after, the remarkable influence of this agent was fully tested and
proved, in most of the public hospitals in this country. Wherever the
news was carried, and the agent was at hand, a trial was speedy and
the result satisfactory, and the only doubt that remained on the
subject was as to the amount of danger involved in its use, or as to the
condition, temporary or otherwise, of the patient’s system, which
should admit or forbid its application. While facts were rapidly ac-
cumulating, experiments were being made by various zealous persons
on the virtues of other agents supposed to have similar influences.
Among them chloric ether was the principal, when Dr. Simpson, of
Edinburgh, who had already resorted to anaesthesia (by ether) in
Midwifery, made use of chloroform with the effects seemingly superior
to those obtained from any other agents hitherto tried. On the 10th
of November, 1847, Dr. Simpson brought the subject before the
Medico-Chirurgical Society of Edinburgh; and on the 15th of the
same month the late Professor Miller performed several operations in
the Royal Infirmary of Edinburgh, under circumstances which at
once established the character of the new anaesthetic. In a few days
chloroform was tried in most parts of these islands, and from that
time to the present it has held an ascendency over every other agent.
It was not long before it was found that danger and death occasionally
followed its use, and many laudable attempts have been made to
render its administration less hazardous. Other agents have been
sought for, and a variety have been specially recommended. The
late Dr. Snow used anylence, but death having occurred under its
influence, it was abandoned. In recent times Dr. Richardson has
introduced bichloride of methylene as a safe and potent substitute, and
for short operations, such as extracting teeth, nitrous oxide gas has
come largely into use, particularly among dentists. In America
sulphuric and chloric ethers are still preferred in ordinary surgery,
but, in as far as I know, chloroform has still the preference among
British surgeons.

While the custom of rendering patients insensible to pain, during
the performance of surgical operations, has rapidly gained an un-
doubted and sure position, there have been various questions and
drawbacks regarding it, many of which are, even at the present day,
of great practical importance. Many deaths have occurred, to all
appearance, directly from the anaesthetic agents, or the mode of their
administration.
administration, and there has been much discussion on both these points. In the early application of ether, a complicated apparatus was used, but soon it was found that by holding over the patient's nostrils and mouth, a handkerchief, napkin, or piece of sponge, moistened with a few drops of the anaesthetic, the desired effect was speedily produced, and, to this day, perhaps the majority of those who use the agent are content with this mode of administering it. From the commencement it has been the custom of most surgeons in large operating practice to have the agent administered by some one whose sole attention shall be given to its physiological effects on the patient during the performance of the operation; and among those who have performed this most important duty, there are few so distinguished as the late Dr. Snow. That gentleman, who was justly deemed our highest authority on the subject of anaesthesia in surgical operations, used an apparatus, being of opinion that there was less danger and more certainty thereby than with a napkin. Mr. Clover, whose experience in the administration of anaesthetics has been varied and extensive, uses an apparatus, with a measured mixture of chloroform and air, which acts with great certainty and precision, but there are different views on these subjects, which need not be discussed here, and it may be sufficient to say that in whatever way the agent is called into use, its powers are fraught with subtle and imminent danger, unless the greatest caution be taken. For my own part, I think it of little consequence by what means the agent is administered, provided there be a fair proportion of atmospheric air admitted to the lungs at the same time, or that there be the facility of admitting it, when the influence of the chloroform, or whatever agent is employed, seems too powerful.

At one time it was supposed that certain states of the constitution, certain conditions of the disease, or affections of certain organs, must preclude anaesthesia in surgical operations, but experience has shown that these fears have all been groundless. The age of a patient forms no objection to its use, for it may be given during the first few weeks of life, or at the latest imaginable date. Nor does it appear that positive disease of any organ forms an insuperable objection to its use. There are certain circumstances in the state of the constitution which will deter the surgeon from performing any important surgical operation, and in such instances the propriety of anaesthesia need never be discussed; but as a general answer to all questions on this score, I am disposed to say, that in whatever ease a surgeon may consider an operation justifiable, the use of chloroform (this is named as the agent in most common use) is equally justifiable. If the operation be of minor importance, and of momentary duration, especially if the patient be courageous, and perhaps averse to the practice, the surgeon need say little on the subject; but in all cases where much and protracted suffering is likely, anaesthesia should be recommended. It will not only save pain, but avert shock, and, provided the agent be properly administered, it will render the surgeon's duties more easy of accomplishment. There are few operations in which its use is not admissible and advantageous. In operations for cataract, especially
by extraction, it is possible that it may prove injurious, as vomiting may be induced and there is no certainty as to the movements of the eyeball and lids for some time after. I have used chloroform for removal of tonsils, in young persons, but the operation is thus rendered difficult, and if the patient will keep steady otherwise, it had better not be used. In staphyloraphy, the co-operation of the patient is so essential that I deem anaesthesia of questionable utility. It has been alleged that there is danger from blood trickling into the larynx and trachea in operations under anaesthesia. In one instance, in the early days of chloroform, I took some alarm on this score, in a case where blood was trickling from the posterior nares into the trachea and causing cough, but I now feel certain that there was no just cause of apprehension. I have since repeatedly removed both upper and lower jaw, and done many other operations, involving considerable hemorrhage towards the throat, but have never seen any greater inconvenience from such a cause than if chloroform had not been used. It has happened repeatedly in former times, that persons have died during the performance of operations. Mental emotion, shock, hemorrhage, have each and all had their influence; but, notwithstanding the various instances in which death has happened under chloroform, it may be doubted if sudden death, during operation, has occurred so frequently since the introduction of anaesthesia, as prior to that date. In my own experience I have seen several patients under chloroform in great jeopardy—one of these had a protracted operation performed for resection of a joint, and possibly a similar state of prostration might have resulted without the use of this agent. In the other instance, tracheotomy was required for disease of the larynx, and under the chloroform, respiration became so slow and difficult that it was feared the patient would die on the instant, before the operation could be executed. When the trachea was opened, he immediately breathed more freely, and speedily rallied from his alarming condition. In other instances I have had reason to think that the agent had been too liberally administered.

The immediate effect of tracheotomy corroborates the view entertained by Ricord and others, that this proceeding may be resorted to with advantage when there seems danger from chloroform. Undoubtedly respiration is of vast consequence under such circumstances, although there is reason to believe that the heart's action may be paralysed whilst respiration is actually going on. When death has occurred seemingly from this agent it has been very speedy, and chloroform leaves the system so rapidly, that if the patient has once become conscious, I doubt if death could ever be attributed to this cause. Anaesthesia has no influence whatever either in retarding or accelerating the healing of a wound. We have no statistical data on this subject, but altogether the impression on my mind is, that a patient is better off with it both under and after an operation than if he were without it. When an operation is contemplated under chloroform, almost the only precaution worthy of being taken is, that food should be avoided for several hours before, as with a full stomach
sickness is likely to ensue. So much has been written on the subject of chloroform since its introduction, that I deem it unnecessary to say much more regarding it at present; and I trust from what has been stated, that it will be understood that, with the few exceptions above made, and such others as might incidentally arise, the inducement of anaesthesia is recommended as an invariable accompaniment of all surgical operations involving considerable pain.

The quantity of chloroform required for different patients is very variable. A few drops may suffice for some, while draçhms may be needful for others, and generally the amount will be in proportion to the duration of the operation. Some persons take it kindly, even greedily; others make great objection and resistance to its use, both while conscious and unconscious; but all can be at last so thoroughly overpowered by its influence that, compatible with respiration and circulation, the greatest imaginable quietness can be obtained. There is very little effect on the pulse in such cases; sometimes it is slightly excited at first, and if the dose be very potent, it may become slow and weak. There is greater effect on respiration. In some, in the early stages, the movements are rapid, and there seems an eagerness to fill the lungs with the vapour. In others a tickling cough is excited. In many, the full effect is induced with as slight a perceptible change as if sleep had suddenly come on; but in many others great irregularity in the respiratory movements ensues, and much cerebral excitement is induced. Rapid breathing may happen, as already mentioned, but the reverse may be the case, and the power of inspiration may suddenly seem to have ceased. For many seconds there may be no seeming attempt at respiration, but at last a deep breath is usually taken which makes amends for the previous cessation. The cerebral excitement is evinced by crying, bawling, singing, laughing, incoherent talking, and with many there seems some prevailing idea which calls forth unusual and often great muscular action. Some strike forcibly with the fists, and with no seeming want of skill; others use their lower extremities, and others again make such violent general struggles as necessitate the greatest muscular exertion in those around to keep them steady. Often these violent struggles, and the temporary cessation of respiration, fall together, and to those not accustomed to such scenes, it appears as if immediate dissolution were impending; but in all such cases a little more of the vapour induces all that quietude which is characteristic of its full effect for the surgeon's purposes. There are various ways in which it may be decided that this period has arrived. Muscular relaxation is one of the best, but perhaps there is no test equal to that of touching the surface of the eyeball with the point of the finger. If there be any indication of feeling, the proper time has not arrived; if the contrary, then the surgeon may proceed. The agent must be administered during the operation as may seem necessary, and it is best to continue its influence until all risk of pain, at the time of operation or dressing, has passed. In most instances it is highly desirable that the patient should be placed in bed before awaking from his anaesthetic trance. In many cases much mental and
bodily suffering may be avoided by administering the chloroform before the patient is moved from bed. In painful diseases of joints, such as of the knee, there is often great suffering in carrying the patient to the operating table, which may, however, be avoided by using chloroform before he is disturbed. Some patients become conscious in a few minutes after the surgeon has ceased his work, while others remain for a longer period as if in calm sleep. In certain instances headache and general uneasiness are complained of for hours or even days after chloroform; but in the majority of cases the effects are slightly if at all felt when consciousness returns.

Soon after the discovery of anaesthesia, when it was seen that death occasionally resulted, it was suggested by Dr. James Arnott that cold, applied locally, would so deaden sensation that operations might thereby be rendered painless. The combination of ice and common salt, so well known to produce a low temperature, was advised as an application over the parts involved. These were placed over the skin, so that they might mingle, or were mixed together in a bag or bladder, which could be laid on the surface about to be cut. In recent years cold has been ingeniously used and recommended by Dr. Richardson, produced by the rapid evaporation of the spray of sulphuric ether and other volatile fluids. The practice suits well for superficial incisions, not involving much nicety in the application of the knife, such as in opening abscesses, or dividing skin in erysipelas; but it is worthless in operations requiring careful movements among deep-seated parts. Cold may be applied to these parts as readily as to the skin in many cases, but the hardness and immobility of the structures thereby induced, are adverse to those manoeuvres which constitute the finer steps in a properly conducted surgical operation. The plan has been much talked of and vaunted by those who rarely, if ever, perform operations; but it is trifling with operative surgery to refer to it as generally applicable.

CHAPTER III.

HEMORRHAGE.

MEANS AND INSTRUMENTS FOR SUPPRESSING HEMORRHAGE.

To save constant repetitions afterwards, to serve the purposes of this introduction, and to illustrate the nature and treatment of certain injuries and diseases, I shall here refer to hemorrhage,—a subject of the deepest interest to the surgical practitioner.

The term hemorrhage implies the escape of blood from a vessel or vessels in any part of the body, but the following observations apply almost solely to those bleedings which occur in the practice of surgery. The loss of blood may be so trifling that it may go on for years without producing any marked effect on the constitution, as is often seen in cases of bleeding piles; or it may be such as to threaten immediate
dissolution, as happens in surgical operations, and accidental wounds involving vessels of magnitude, or in cases of severe epistaxis: the escape may be from a single vessel or from many at the same time; an artery or a vein singly may be the source of hemorrhage, or both may pour out their blood simultaneously; the occurrence may be the result of spontaneous rupture; the vessels may be torn, cut, or bruised,—they may be partially wounded or completely divided; the bleeding may be the immediate result of an accidental injury, or of a wound inflicted by the surgeon, in which cases it is termed "primary;" or it may happen within a few hours or days thereafter, when it is called "intermediary;" or it may occur as the result of sloughing or ulceration, when it is said to be "secondary."

Hemorrhage, under each of the circumstances here alluded to, is of frequent occurrence, and there is no single department of the surgeon's duties which requires more skill, decision, and promptitude. As the subject will be frequently referred to in after pages, the remarks upon it in this chapter will be chiefly of a general character, and moreover will have reference principally to treatment.

The means and instruments for temporary suppression of bleeding from wounded arteries (the most troublesome and also the most formidable occurrence in all cutting operations on the living body), are few and simple, in the hands of a good surgeon. In amputations of large portions of the extremities, a slight degree of pressure with the fingers or thumbs will, if judiciously applied over the main artery, be sufficient to arrest the circulation for the time.
FOR SUPPRESSING HEMORRHAGE.

On the upper extremity, with the fingers thus (fig. 31), and their points properly placed over the artery, a very slight force suffices. Any part of the arm may be selected, but that here pointed out will be best if the circumstances are otherwise favourable.

In all amputations of the lower extremity, when such pressure is required, it had better be made on the brim of the pelvis, thus (fig. 32); if made lower down, additional force is necessary; and, even then, especially if the thigh be fat and muscular, it is not always effectual. Occasionally the circulation is stopped in the leg by thrusting the fingers into the ham; but unless the patient be much emaciated, and considerable force is used, the plan is far from being a certain one. Some consider it advantageous to compress as near the place of operation as possible, in the likelihood of less blood being lost than when done at a distance; the principle is a good one, when judiciously acted on; but, in attempting to put it into effect, care must be taken that no impediment is cast on the due performance of the operation—as by preventing a proper retraction of the soft parts—and, also, that the pressure is not applied in a situation where it will be of little or no avail.

In the generality of instances, I prefer having the pressure applied over the brim of the pelvis; considering that the ease and efficiency with which it is done are fully equivalent to the loss of the small additional quantity of blood, intended to be saved by applying it lower down.

In either the lower or upper extremity compression may be applied in a variety of places, as will be afterwards explained in describing the different amputations and other operations.

For the purpose above alluded to, most surgeons prefer the tourniquet (fig. 33), as being in general more trustworthy than the fingers of assistants, which in protracted operations become fatigued and benumbed.

On the upper extremity the tourniquet is generally applied about the situation indicated in figure 34; but any other part between the armpit and elbow will, according to circumstances, answer equally well.

On the lower limb, the place usually selected for the application
of this instrument is the upper third of the thigh, as represented in sketch 35. If amputation in the thigh is to be performed, it should be placed as high as possible; and it should always be re-membered that its presence impedes the retraction of the soft parts. In amputations of the leg, some place it on the lower third of the thigh, a large pad, proportioned to the depth of the popliteal space, being used on the occasion, and I generally give preference to this situation in such cases. If the operation is to be done on the foot, and a tourniquet be thought requisite, it may be applied with proper effect immediately above the ankle, one roller being placed over the anterior tibia artery, and another over the posterior.

If the instrument is properly applied at the knee, in the position

Fig. 34. Fig. 35.

represented in figure 36, amputation may be performed anywhere between the knee and ankle, without the loss of a single ounce of blood; and so far from the pressure being less effective in this situation than elsewhere, I deem it the most eligible of all the extent of the lower extremity, when the operation is to be done below the knee.

The tourniquet may be applied to either extremity, as exhibited in the accompanying sketches, in the following manner: a pad, such as is seen in sketch 33, on the strap of the instrument, may be used; or, what I consider better, a hard roll of calico (such as is exhibited in the other cuts,) about two inches in length and one in thickness, is to be put on the skin over and parallel with the course of the main artery, and secured there by one or two turns of its free end: the strap of the
instrument is then to be carried round the limb, and fastened by means of the buckle, when the requisite amount of pressure can be applied by turning the screw. The latter movement effects the separation of the two plates with which the strap is connected, and whilst thus diminishing the circumference of that part which is round the limb, at the same time forces the roller against the artery. But if care be not taken in its application, there may be as much danger in trusting to it as to the fingers. The metal and strap of this instrument must be strong enough not to break on the application of any reasonable degree of force. It seems to me of little consequence on which side the screw is placed: some prefer it over the main artery, others directly on the opposite surface of the limb, but in any way the roller or pad must be directly over the vessel, and the buckle must not be so close to the plates as to come in contact with them when the screw is turned. After the vessels are cut in an amputation, it is sometimes found necessary to apply additional pressure, which could not possibly be done were the buckle close to the plates. It is of consequence, too, that when the strap is fastened in the buckle, the screw should be immediately turned, for a very slight pressure round the limb—even that occasioned by the weight of the tourniquet—will retard the circulation through the veins, especially in those which are superficial; and thus whilst the blood still passes in its usual full stream, into the lower part of the limb, a considerable accumulation occurs in the veins below the instrument, and a larger quantity is lost during the operation than can be deemed in accordance with the patient's safety.

There are other pieces of apparatus which may be used for the same purposes as the tourniquet, but the above, since its invention by Petit, has generally been considered the most perfect, and it is an instrument which every surgeon should have in his possession. Though he may dispense with its use when surrounded by able assistants, and is himself possessed of great self-confidence, he may, on some occasions, have reasons to regret that one has not been at hand; or even should this never be so, he will, at best, only display a degree of foolish vanity in his own resources or good fortune, if, in vaunting his temerity, he
attempts to bring into desuetude an instrument which has the sanction of the highest authorities, and which has been so long considered indispensable in the practise of surgery.

Various pieces of mechanism have been used and recommended as tourniquets; but I know of none worthy of superseding that just referred to. A very ingenious and simple contrivance (fig. 37), by Dr. Signoroni, of Padua, has been constructed by some of our instrument-makers. It consists of two elliptical bars, joined at two ends by a kind of hinge, where they are so acted on by a screw, that the other two ends, which are properly padded and covered with cloth or leather, can be opened and shut at will. I have made numerous trials of this machine during amputation, but see no reason to alter the opinion above given, regarding the ordinary tourniquet.

The tourniquet of Petit (fig. 33) embraces tightly the whole limb, and prevents all circulation in the part beyond where it is placed; on that account its prolonged use might be dangerous or destructive to the member, and it can only be employed as a temporary means of suppressing hemorrhage. It may be desirable in some instances to impede the flow of blood through the principal vessel of a limb, at the same time leaving all other parts so devoid of pressure as to permit free collateral circulation. The fingers may be used so as to have this effect, as has been admirably evinced in the modern treatment of aneurism; but uniform pressure cannot be long sustained by manual force, and the instrument of Signoroni which acts on this principle may be effectively applied, and has been used with admirable results in the treatment of external aneurism, as will be afterwards explained in the chapter on that disease.

For the permanent suppression of hemorrhage the open ends of divided vessels must be secured by some local mechanical obstruction, and that in most common use is the ligature, which should be applied in the following manner. Each artery which is not likely to cease bleeding without this measure, is to be taken hold of with the common dissecting forceps, held in the right or left hand of the surgeon,
drawn slightly out of its sheath, and separated from the vein or veins in contact with it, when a thread is to be tied round it by an assistant, a little beyond the point of the instrument, with a degree of tightness that will prevent the noose from slipping; and thus each vessel may be closed until nature effects its permanent obliteration.

The thread for a ligature should be a small round cord of hemp or silk, about fifteen inches long, possessed of sufficient strength to allow of some force being used in drawing a compact noose, and forming a firm knot. The thread should be tied in such a way that it will not loosen, and for this purpose the surgeon's knot (fig. 38), as it is called, may be applied. This is made by passing one end of the thread twice over the other, before turning each end back again to form the second noose; but it seems little used by surgeons of the present day, perhaps in consequence of what was stated by Boyer, that Chopart, in the presence of some of the most distinguished professors in Paris, in operating for popliteal aneurism, could not completely restrain the flow of blood by tying the surgeon's knot; a second ligature was applied, and then a third, without success; when, after some deliberation, it was thought advisable to amputate, as it was supposed that the artery was so ossified, that it would not close with a ligature. On examination of the vessel after the operation, it was found in a natural state, and that the knots had not completely closed the canal. For my own part, however, I can scarcely understand how, with a ligature of such bulk as we use in the present day, such a defect could occur; but though I set little importance on this explanation, I decidedly prefer the sailor's or reef-knot, as exhibited in figure 39, which, when the noose and loops are drawn tight, will make all secure; but there can be no harm in fastening a third turn of the ends, when there is the slightest apprehension of slipping. One end of the thread should then be cut off, and the other left hanging out of the wound. In all instances, where a wound is dressed with a view to union by the first intention, this plan is preferable to that advised by Dr. Hennep and others, of cutting away both ends of the ligature, close by the knot; and so far as my experience goes, I would rather even permit both portions to remain than leave the noose to find its own way to the surface,—a process which is sometimes both tedious and troublesome, as well as the source of much anxiety and pain to the patient. Taking into consideration the injury inflicted, and the extent of wound when a ligature is required, I deem
the presence of one, or even both of its ends, a matter of little additional consequence. I have on many occasions left both ends of a ligature on the main artery hanging out of the wound, as was the custom before Mr. Veitch proposed to remove one of them, without having had cause to regret doing so, and in instances where numerous ligatures have been applied, have had more trouble with some small part of the wound (perhaps the aperture of a stitch) than with the tracks of all the ligatures used. When a wound is expected to heal by granulation, both ends may be cut away; but even here, though I often practise the plan, much annoyance may be caused by the noose remaining imbedded in the granulations.

The ligature which I generally make use of is small, smooth, and well-spun twine, which, as it comes from the manufacturer, is sufficiently stiff, without the aid of bees-wax, to permit a noose to be east without trouble from the ends being too limber. Silk may be used, but it should not be supposed that the finer material produces no irritation in the wound; indeed I think that some surgeons have been far too nice regarding the size and material of ligatures. In my own practice I am in the habit of using a greater number of ligatures than is the custom of many other surgeons,—often preferring the thread to the chance of the vessel closing naturally, and I feel bound to say, that on no single occasion have I ever had reason to suppose, that any subsequent unpleasant occurrence has been in any way attributable either to the size or number of ligatures. I do not wish it to be imagined, however, that I am an advocate for thick ligatures, or for applying more than may be reasonably deemed proper; but I decidedly recommend a substance of such bulk that the person who uses it can, in the bustle of an operation, readily feel that there is something between his fingers. Fine dentists' silk is objectionable on the latter account, and also because it may possibly cut the textures through altogether, instead of merely making a groove as the other does, sufficient to keep it in its place, until it is separated by nature. Mr. Lawrence recommended fine silk, with the object of cutting away both ends of the ligature, and having the smallest possible size of foreign substance (the noose and knot) in the wound; but although the objections stated above may be avoided, by great care, and by not pulling too hard, I cannot see any particular advantage in the plan, even though the part left may not weigh more than \(\frac{1}{30}\)th or \(\frac{1}{40}\)th part of a grain. In my own cases, in removing both ends (for I have frequently done so), and more particularly in witnessing the practice of my former colleague, Mr. Lizards, who invariably removed both ends in all kinds of wounds, I have not in every instance seen bad results follow; on the contrary, many wounds thus treated, healed as kindly as could possibly be wished; but I nevertheless believe, that they would have healed equally well had the ends been left on. Sometimes the foreign substances probably remain in the cicatrix, but much more frequently they are carried away in the discharge, either during the first healing of the wound, or by a subsequent process of suppuration. It may happen that a wound will at once close over a thread left in this condition; but in the course of
a few weeks or months, inflammation and swelling come on, then suppuration, and when the abscess is opened, or bursts of its own accord, the noose will make its appearance. This result forms, in my opinion, the principal objection to the practice; if, for example, a patient who has undergone an operation for a scirrhous mamma, be dismissed after the lapse of three weeks or a month, with the wound healed, and some time after a painful swelling and suppuration occur in the cicatrix, she naturally supposes that there is a return of the original malady, and will not be convinced to the contrary until the abscess has closed; and as it may even then be uncertain if all the knots are away (for they cannot always be seen, or may be overlooked, in the discharges), she may, during the lapse of a considerable period, still dread that she will again suffer in the same manner. Mr. Guthrie expressed himself
decidedly averse to this plan, and Sir George Ballingall alluded to a case which is, in my opinion, corroborative of the views above expressed.

In recent times the plan of cutting off both ends of a ligature has been most satisfactorily applied in ovariotomy, particularly by Dr. Tyler Smith. The neck of the tumour has been surrounded by a stout thread, and after a tight noose has been drawn, the ends of the ligature have been cut close to the knot and the pedicle has been allowed to glide into the peritoneal cavity. I have tried this process in my

own practice, and it has answered admirably, nor am I aware of any instance where evil has been attributed to it.

Instead of the ordinary forceps, an instrument with a slide or catch upon it (figs. 40 and 41), will occasionally be of service, when no competent assistant is near. When the artery is seized, the blades will remain shut, and the instrument may be allowed to hang till a ligature is applied. The catch may be so put on that it can be slipped out of the way, or turned aside, to allow the instrument to be used, at the will of the surgeon, like the common forceps. The blades may be hooked at the ends, as in fig. 40, or made flat and rough, like those represented in fig. 41. Various ingenious contrivances exist to make this kind of forceps efficient and of general utility, all of them being modifications of the instruments used by Amussat, in torsion of the
arteries,—a method of arresting hemorrhage which, though it has been much practised on the Continent, has never yet received the sanction of English surgery, and which seems to me to possess such trifling advantages over the ligature, as to induce me still to prefer the latter. The hook-like point of the forceps, as shown in fig. 40, is admirably fitted to seize and hold firm any object, such as an artery, and I have found these forceps, either with or without the catch, of invaluable service in removing small tumours from the neck, axilla, and other such parts, where it is desirable to draw the swelling well out, before using the knife to divide the textures behind.

It will be observed that these forceps, and the common ones referred to previously (p. 5), are narrow and slender at the point. This occasionally gives rise to inconvenience during the application of ligatures, for the noose is sometimes tied round the point of the blades, instead of the artery. To obviate this annoyance, an old-fashioned shape of forceps has been revived again by some. The blades are kept about half-an-inch broad, until nearly a similar length from the end, when they rapidly diminish to a point, like that on the ordinary instruments. Such a shape gives a clumsy appearance, but this has in some degree been obviated, as is here represented (fig. 42), in an instrument constructed by Mr. Coxeter, of University-street. When an artery is seized with such blades, the noose which is made on the ligature must slip over the point as it is tightly drawn, and so the inconvenience often felt with the other blades is done away with.

*Fig. 42.*

*Fig. 43.*

But it sometimes happens that the vessels cannot be readily got hold of with the forceps, or cannot be drawn out of their sheaths, so as to allow a thread to be applied. A pointed hook or tenaculum (fig. 43) will then be of advantage; some even prefer it to the forceps on all occasions. The sharp point is thrust through the bleeding vessel and some of the surrounding parts (for we can scarcely avoid including some of the neighbouring tissues where all are thickened and matted together) and then raised, so that the thread may be tied beyond the convexity.

Of these methods I give the preference to that with the common forceps, and either of them I consider superior, both in point of facility and security, to that of twisting the ends of the vessels till the blood ceases to flow. Whichever
instrument is used to seize the vessel about to be surrounded with a ligature, the utmost care should be taken to exclude all the neighbouring tissues,—veins, nerves, sheaths, or others, and this, in my opinion, can be most readily done with the forceps. Including the artery alone in the ligature may be justly alluded to as one of the characteristics of modern surgery. I do not myself look with such dread upon the inclusion of a vein, and even other tissue, with an artery in the same noose as some do, but as it is not required, and may possibly be the cause of after mischief, it ought never to happen when it can be avoided.

Torsion of the main arteries, to suppress hemorrhage, seems to have gained few advocates among British surgeons, notwithstanding the examples of Velpen, Fricke, Amussat, and others on the Continent; and so far as my experience enables me to judge, I have never seen reason to prefer this plan to that with the ligature. Small vessels may be advantageously treated in this way, and such a plan has been long followed. I cannot, however, perceive any advantage in the practice. The objection to the ligature is, that it is a foreign body, but I doubt if the same objection may not be raised to torsion, for in order to make this process secure, the vessel must be twisted to

Fig. 44.

such an extent that, in all probability, its vitality is destroyed, and the slough thus occasioned must prove equally injurious as a ligature. Supposing that torsion and the ligature are productive of much the same extent of local injury at the time, and subsequent mischief, it seems to me that the ligature gives such an amount of temporary security, that it ought as a rule to be preferred. When a vessel is easily pulled out of its sheath, torsion is readily effected; but the same is the case with the application of a ligature. If, perchance, it is desired to try this plan, it may be effected thus: the artery to be so treated is to be seized with the point of the forceps, pulled out of its sheath, and twisted probably some eight or ten times, until it will not become undone. In this way, however, which was that followed by Fricke, the twist may reach further up the vessel than may be desired, and to prevent this, the method recommended by Amussat is, to grasp the artery across with another forceps, thus (fig. 44): the instrument which is used to pull the vessel from its sheath should be parallel with the axis of the artery, the other should grasp it at right angles about a quarter or half an inch higher up, and both should be provided with a catch to keep the blades firmly closed. The transverse blades keep
the vessel steady, while with the other instrument the twisting is continued to the desired extent. The process of torsion has been recently revived by Mr. Syme, and interesting papers have been written on it by Mr. Bryant, of Guy's Hospital, and Mr. Humphry, of Cambridge, but I have not as yet learnt anything to induce me to modify or change the opinion above given.

In arresting the flow of blood to particular parts, as for secondary hemorrhage after amputations, or in the operation for the cure of aneurism, when the main artery is cut down upon at a distance from the disease, an instrument of this kind is generally used,—the common aneurism needle (fig. 45), as here represented. Various sorts and shapes are recommended by different surgeons; but one like the sketch will be found most convenient for general purposes. The metal should not bend nor break with moderate force, and the eye should be near the point, and sufficiently large and smooth to let the thread glide easily through it. The point itself should not be so sharp as to endanger either artery or vein; and the handle should resemble that of a common scalpel.

When a ligature is applied to an artery, the nearer it is placed to the neighbouring textures, so much the better; great care should be taken, however, that none of these are included, particularly the veins and nerves; and, in operations for aneurism, the less an artery is disturbed in passing the needle and thread under it, so much the more favourable opportunity is supposed to be given to its permanent closure, as the less that the surrounding vessels are interfered with the greater is the chance of permanent closure of the vessel by adhesion.

In some rare and troublesome cases of bleeding, when the vessel or vessels cannot be seized with the forceps, it is necessary, in order to arrest the flow of blood, to pass a needle and thread through the textures on each side, so as to include some of the surrounding parts in the noose. Common surgical needles, such as are here represented (fig. 46), or one of this sort (fig. 47), set in a handle like that of the aneurism needle, as represented in fig. 45, may be used for this purpose. If the parts be deep-seated and difficult to reach, the latter form will be most convenient, particularly if some considerable force is required to push the needle through the textures. In passing threads through small tumours, too,
such as naevi and hemorrhoids, this kind of instrument will be found exceedingly convenient.

When these latter means are resorted to, a little more than the bleeding vessel must necessarily be included in the ligature; and though, in general, this circumstance is of no great moment, the rule in surgery ought never to be forgotten, of including the bleeding vessels only, when such a proceeding is practicable.

The end of each thread should be cut with scissors, as when a knife is used for the purpose, however sharp its edge it may drag out the parts, and actually separate the ligature. The common dissecting scissors (p. 4) will answer; but there may be danger in some cases from the sharp point, and such as those here exhibited (fig. 48), which, for

Fig. 47. Fig. 48. Fig. 49. Fig. 50.

the sake of distinction, I shall call the surgical scissors, had better be employed. Their length should be between four and five inches, and the angle near the hinge will be found of advantage on many occasions: indeed, this shape I deem far the most convenient for a pocket case, as it serves nearly all the purposes to which scissors are applied. In cutting plasters, the blade may be run along without touching the surface with the hand, and bandages and dressings on a limb can also be cut without the danger of running the points against the skin, as might happen with straight blades. But the shape of scissors is much varied, according to the views or fancies of the surgeon, and amongst many that I have in my hands from time to time, I may allude to shapes like these. The curve of fig. 49 is very serviceable in cutting ligatures.
and stitches, or the removal of certain forms of tumours, but that of fig. 50 is most in my favour at the present time.

The above observations have reference chiefly to arterial hemorrhage, and that, too, occurring during operations, or immediately after the infliction of wounds; but the surgeon has other kinds of bleeding to deal with, and his assistance is required at other and equally important times. Although hemorrhage from arteries is that which is most to be dreaded, it cannot be doubted that the wound or rupture of a large vein may be equally prejudicial, and therefore the surgeon, in all cutting operations, is as anxious to avoid such vessels as any other important parts. In operations for aneurism, or for the removal of tumours, he carefully protects the large veins, for the purpose of preventing hemorrhage, and other unfortunate results which may follow their injury; but such veins must often be wounded, or even cut across; as, for example, in venesection, the treatment of varix, in operations about the neck, and in amputation. It rarely happens that bleeding from veins is at all troublesome to arrest, unless it be from vessels of the first magnitude. In venesection at the elbow, for instance, or in the external jugular, the removal of the obstruction to the circulation, on that part of the vessel nearer the heart than the wound, is usually sufficient to permit the blood to take its natural course, and at all events slight pressure with a pad and bandage will have the effect of arresting the further flow from the wound; and so it will have, too, in wounds of larger veins than are interfered with on these occasions, as is exemplified in rupture of varicose veins on the leg, or when the surgeon divides them with the knife; for in such instances slight pressure, combined with the horizontal position, is sufficient to restrain the flow of blood, even when the vessels have been enormously distended.

Perhaps the most troublesome of all venous hemorrhage is that which occurs during operations at the root of the neck (as on the principal arteries), and in amputations near the trunk. In the former case, unless some very large vessel is wounded, the blood ceases to flow from the aperture, as soon as the struggles of the patient subside, and the respirations become more natural. It seldom happens that more than a little temporary pressure with the point of the finger, or in any other convenient mode, is required; when the finger cannot readily be applied, a curved copper spatula may suffice, forceps with a catch may be used, or such an instrument as this (fig. 51), which has been devised purposely for temporary compression. The blades shut of their own accord, and after being opened and placed upon the bleeding vessel, they, by their elasticity, keep their hold with sufficient tightness. Even ligatures may be applied. In the latter case the threads may be drawn with such a tightness only as to prevent the blood from flowing, for it is deemed by some the best plan to remove them, as soon as the chief part of the operation has been accomplished. In some cases the surgeon finds it necessary to allow the ligatures to remain, or to replac
them, in the event of the hemorrhage continuing; but this latter measure should not be resorted to, unless the bleeding cannot be restrained otherwise. It must be remembered that, in the neck, hemorrhage may be equally troublesome from either end of the vein; and on the external jugular, for example, a ligature may be required both on the upper and lower side of the wound.

Venous hemorrhage, during amputation, is commonly most conspicuous when the fingers are used instead of the tourniquet, to arrest the circulation; as the main vessels are then alone compressed, the smaller arteries, given off above, convey a large quantity of blood to the part of the limb below the pressure, and it is apt to run from the corresponding veins into the lower part of the larger tubes, and so escape through their divided extremities. The valves in the superficial veins in a great measure prevent this: it often happens in the deep veins, however; but usually ceases as soon as the fingers are removed. Sometimes it is not desirable to raise the fingers until the large arteries have been secured with ligatures; and in such a case, whilst they are being applied, such an instrument as that represented above may be put on, or what would be better, an assistant should place the point of his finger over the bleeding orifice. At the shoulder, in the leg immediately below the knee, and above the middle of the thigh, the large veins are apt to be troublesome, during the taking up of the arteries; but I have seldom known an example where the bleeding did not cease when all pressure was taken off the main vessels above, and when the flaps were approximated with the stump laid in a proper position. In some instances, as in removing the great toe with its metatarsal bone, I have found it difficult to secure the bleeding arteries in the usual manner; here, in consequence of the hemorrhage appearing partly venous, I have stuffed the wound with lint, and applied a bandage over all with good effect; but this course prevents union by the first intention, and should not, therefore, be resorted to unless the necessity be urgent.

In amputations and in all other operations involving the division of veins, it is seldom requisite to apply more than moderate pressure to stop the flow of blood from the divided ends. Formerly it was the custom to secure the vein and artery in the same ligature, but such a plan is now obsolete, excepting in rare cases, when the surgeon can scarcely do otherwise. For the last thirty or forty years he has, in securing the main artery of a limb, taken especial care to exclude the accompanying vein; and assuredly this general practice, for many good reasons, should never be deviated from; for, although I consider that recent experience in the treatment of varicose veins, as well as in many common occurrences in surgery, goes far to show that there is really no such great danger in interfering with veins as was supposed by those who reasoned on the few fatal results of ligature of the internal saphen, practised by Home and others, as it is rarely necessary to use a ligature to a vein, there is no occasion for inflicting an additional and worse kind of wound upon it, by means of the thread.

For oozings of blood either from veins or arteries, it is customary to trust to local astringents and styptics of various kinds. Cold air, spirits
of wine, resinous tinctures, turpentine, solutions of various salts, such as the acetate of lead, perchloride of iron, nitrate of silver, chloride of zinc, sulphate of alum, of iron, of zinc, or of copper, caustic potash, even the actual cautery, have all been used for this purpose. From time to time pretended specifics have been used also; but with these, as was the case with the famous styptic of Brossard, the agaric, pressure seems invariably to be the main agent; and doubtless it would, if properly applied in a severe hemorrhage, be equally efficient without the aid of the mysterious and empirical supposed styptic. Cold air, or cold water, will generally prove successful in ordinary cases, and the cautery will arrest bleeding from very large vessels; but unless these run in bone, or cannot be commanded in any other way, it is now-a-days seldom used for such purposes. Any of the medicated fluids enumerated above, used diluted or otherwise, will prove styptical in all ordinary oozings. Sometimes they are merely allowed to come in contact with the surface; on other occasions they are combined with pressure, the latter being applied by means of sponge or lint, kept on by the hand or by a bandage. In all instances, the practitioner should bear in mind the favourable influence of keeping the bleeding part above the level of the heart if possible, nor should he forget the supposed effects of the acetate of lead when used internally in such cases, or the peculiar influence of digitalis over the heart's action, and above all the influence of time and loss of blood in permitting contractions of vessels, formations of clots, and reducing diminution of the heart's action.

In many cases the surgeon is obliged to trust either to one or other of these means; but I need scarcely repeat, that when the bleeding is profuse, and when the ligatures can be used with propriety, they should generally be preferred.

The term "intermediary hemorrhage" is but of recent date in surgical language. It implies that bleeding which occasionally takes place in the period between the first dressing of a wound at the conclusion of an operation, and the coming on of inflammatory action. When the surgeon is hurried or careless in closing such vessels as throw out blood palpably on a wound exposed to his inspection, hemorrhage is not unlikely to occur within the first eight hours afterwards, and in some cases to a profuse amount. Much harm may thus result in various ways. The loss of blood may be depressing, and after-evil may be the consequence; or there may be serious apprehension at the time from prostration, or possibly from pressure upon some important organ. At any rate, there will be separation of surfaces and prevention of union by the first intention. I have seen a man nearly choked from accumulation of blood in the wound within eight hours after an operation on the neck; and I have seen a patient die within thirty-six hours after removal of the testicle from extravasation of blood in the course of the spermatic cord. It is a kind of bleeding which has rarely been noticed by surgical authors—possibly because its occurrence has exposed the practitioner to whom it may have happened to a certain amount of blame. It may happen to the most careful and painstaking; but I have generally noticed it, both in my own practice and that of
others, as the result of a certain amount of carelessness or hurry. The most conspicuous instances that I have seen, have been when the surgeon was seemingly anxious to have his patient rapidly off the table. In such examples, the hurried messages from the nurses or dressers in the wards of an hospital have usually denoted what was wrong, and the surgeon or assistants have then been obliged to do what should have been effected at the time of the operation—more ligatures have been required.

In these cases the bleeding has come on as the patient’s circulation has revived with the warmth of the bed and possibly the administration of stimulants; but the real cause has probably been the neglect of the surgeon to secure all bleeding points. In the anticipation of this kind of hemorrhage it would be well were the surgeon to bear in mind that the presence of a ligature, though not absolutely necessary, will be productive of less harm than that of even half a drachm of blood.

Although even now I am occasionally annoyed by this kind of bleeding, I am much less so than in the early years of my practice, because I take much more pains in securing by ligature every vessel which seems likely to let blood escape after closing and dressing the wound. It is partly to avoid this occurrence that some have advocated the proposal not to close a wound until six or eight hours after it has been inflicted, under the supposition that there will then be no further probability of hemorrhage.

Secondary hemorrhage is often more alarming, and more uncontrollable than that which occurs during the performance of operations, or as the more immediate effect of injuries. This kind of bleeding usually happens after amputations, and operations for aneurism, about the period when the ligature separates from the principal artery, and it is a well-known result of gun-shot injuries which involve one or more of the chief vessels of the part. It may ensue in consequence of the adhesive process not having taken place at the seat of ligature or in the otherwise wounded vessel, or it may be the result of unhealthy inflammation, or of ulceration in the wound, causing the vessels to open after having been closed by the proper effusion of lymph. The bleeding which occurs in ulceration and sloughing, such as occasionally happens at the ham, groin, and neck (although it may be for the first time, i.e. primary), is somewhat analogous, as there is a similar unhealthy action—a similar deficiency of adhesion.

When the vessel is small, some ordinary styptic may suffice to arrest the hemorrhage, particularly if combined with pressure; possibly caustic or cautery may be used with advantage; but if it be large, these means are not to be trusted to; the ligature will alone give assurance of safety.

Pressure, when selected, should be applied directly on the bleeding point, by graduated compresses and bandages; and it will be of advantage, too, if it be put on the main artery or arteries leading to the aperture, as on the humeral, radial, and ulnar, in puncture of the humeral during venesection, or in wounds deep in the hand. In some parts of the body, as at the root of the neck, the surgeon cannot do otherwise than trust to pressure, although in such instances he often
has the fatal proof of its inadequacy. When the stream is profuse, he may, on certain occasions, as in a stump, at once see the propriety of resorting to other measures. Perhaps there may be difficulty in deciding on the proper part for the application of a ligature. The occurrence may, in general, be taken as sufficient proof, that there has been little disposition towards the adhesive process, and that, at all events, ulceration and other unhealthy actions, are going forward in the seat of hemorrhage: in such a case, then, it will be advisable to place a ligature on the principal artery of the limb, at a considerable distance from the orifice; in a stump in the leg, for example, the superficial femoral should be tied in the middle, or upper third, of the thigh. The impetuosity of the current is thus stemmed: much less pressure will check the further flow of blood from the orifice (if, indeed, there be any): more healthy action may go on in and around the bleeding vessel, and adhesion, granulation, and cicatrization, will at last close up the parts. In such a case, there may be secondary hemorrhage from the seat of the ligature, and in this event the best skill may possibly be of little avail. Some observations on secondary hemorrhage after ligature of the superficial femoral artery, will be found in a future part of the work, which may, perhaps, serve to guide the surgeon under such difficult circumstances. Possibly, in some such instances, the modern tourniquets used for the treatment of aneurism may be of much service in averting the necessity for the knife. The common tourniquet cannot be depended on for any length of time, as it obstructs all circulation, but that of Signoroni, described at p. 28, might so stem the current in the main vessel as to restrain the loss from the open orifice below.

Since the last edition of this work was published the subject of hemorrhage has attracted more than usual attention in consequence of the proposal made by Sir James Simpson to use pressure instead of the ligature to stem the flow of blood from wounded vessels,—the pressure being applied by means of needles passed through the soft parts in various ingenious ways so that the needles compress the vessels sufficiently for the object in view. Thus, in amputation in the thigh or arm, the point of a long needle, such as might be used for harelip, or longer and stronger if thought desirable, is thrust through the flap containing the principal artery, and when seen on one side of the vessel is turned up with a sharp curve so as to include the artery, and finally pass through the skin a little to the inner or outer side of its introduction. The soft parts are so squeezed by the fingers as to permit such a manipulation to be readily accomplished, and when these needles and the parts are left alone, between the stiffness of the needle and the disposition of the tissues to resume their normal position a degree of pressure is effected on the artery sufficient to prevent the blood escaping. Such other vessels as might be considered likely to bleed are compressed in a similar manner, and thereafter the surfaces are brought together with the hope that union by the first intention (or without suppuration) will take place. Sundry modifications of this plan have been proposed by Sir James Simpson
WOUNDS.

and others in order to suit the variety of circumstances in wounds, but the principle of all is that the needles shall be removed within a brief period of their introduction—from a few hours to two or three days, so that they shall not act as foreign bodies as ligatures do.

Few original thinkers have backed up their proposals with so much material or so much proof as the author of this plan, to which he gave the name of "acupressure." Within a few years of its inception he published a large octavo volume on the subject, containing proofs of its seeming efficiency, which could admit of no denial. These evinced that the largest vessels, divided in all parts of the body in usual surgical operations, could be compressed effectually on the living frame; and a subsequent publication by Messrs. Keith & Pirrie, of Aberdeen, has added strong corroborative evidence. There need, there can be no doubt regarding the efficacy of this plan when properly carried out, and its principle is a pleasing and valuable advance in surgery.

Sir James Simpson introduced this practice with a seeming demonstration of the evils of the ligature sufficient to make many shrink aghast at what may have been done with this method—a method which made its author suppose himself inspired when he first imagined it. His main arguments are to the effect that the presence of ligatures prevents union by the first intention, then induces suppuration, and so a material is developed which being (and very often as he alleges) absorbed into the circulation, produces a poisonous effect, which either seriously retards the cure of a wound, endangers life, or absolutely destroys it. With acupressure he maintains there are no such evils, that the wound of a needle is hardly worth consideration; that no evil—particularly no suppuration—comes from it if removed within the first 24, 48, or 72 hours from its introduction, and that thus all the dangers hitherto considered inherent in wounds are evaded.

The practice has been extensively followed in Edinburgh and other parts of Scotland, particularly in Aberdeen; but as yet the faith of the majority of the surgeons in the ligature has been such as to induce a preference for it, and although few, if any, question either the practicability or efficiency of acupressure when it is properly applicable, many remain unconvinced of its alleged advantages and superiority.

CHAPTER IV.

WOUNDS—TETANUS—SUTURES—DRESSINGS.

Wounds constitute a large proportion of the field of surgery, and although much of the after part of this work is devoted to the consideration of particular kinds of such injuries, I deem it proper, in this stage of my work, to make some general observations upon them.

The ordinary definition of the term wound is, "a solution of con-
tinnitus in any of the textures of the body induced by violence," and this includes all kinds of injury, from the slightest abrasion or contusion to the most extensive incisions or lacerations. In one instance the separation of tissues is apparent in the shape of a gap or recent wound on the surface, which is exposed to the open air; in another it is deep-seated, and the divided parts may never at any time be thus exposed.

Surgeons have usually recognised wounds under the characters of incised, punctured, contused, lacerated, poisoned, and gun-shot, as each of these possesses some peculiarity whereby it is distinguished from the others.

The incised wound is such as has been inflicted with a cutting instrument, and is usually deemed the simplest of all. But in this latter feature much will depend on its locality and the parts which are injured. Neither can the danger of a wound of this kind be estimated by the apparent size of the gap, for the most slender cutting instrument may reach the interior of an important joint, possibly one of the large serous surfaces, or a main vessel or nerve.

The punctured wound differs from the incised chiefly in the circumstance that the separated tissues are torn from each other, and those in the immediate vicinity are more or less stretched and bruised. The injury to the textures is more severe than in a simple incision, and the danger will be in proportion to the depth and the nature of the parts implicated. In either instance the effects may be greatly influenced by the condition of the instrument or object which has caused the wound.

Contusion and laceration are so much alike, that it is difficult to point out a distinction. In both kinds of injury the textures are torn asunder, and the extent of damage of this sort is usually greater than in the punctured wound. The term contusion is generally used when there is no breach on the surface, and that of laceration when such is the case. In the latter example the injury may be deemed more severe, but yet it may be that the contusion of the parts underneath is the most serious feature of the two. Whether a wound be termed contused or lacerated, there must always be a combination of both. Each is easily recognised if it be on or near the surface. The open breach and the history of the injury will sufficiently indicate laceration, and the contusion will be characterised at first by the flabby condition of the part which has been struck, and latterly by the discoloration and swelling—each of these last-named features being the result of the effusion of blood which has taken place from the contused and lacerated vessels. The danger of contused and lacerated wounds will be in proportion to the extent and the nature of the parts implicated. A contusion may vary in its character from the slightest discoloration (ecchymosis, as it is called) of the skin to an amount of injury involving the entire thickness of the part. It may happen also in such cases that the bruise kills the tissues at once, and these, if left on the body, must be separated as sloughs. A laceration may vary from a slight scratch to an injury of fearful extent, involving the removal
of a great portion of the body. Parts may be more or less extensively severed from each other, or a portion of the frame may be completely torn off and separated from its living connections.

A poisoned wound is characterised by the presence of some material (the poison), which is of itself the principal source of danger. The wound is seldom of much magnitude, being usually in the shape of a puncture or scratch, and the poison exercises its influence on the system either through the medium of the nerves or in some other mysterious manner, as in the instance of the bite of a poisonous snake, or a rabid dog, or by inducing a formidable inflammation, usually of an erysipelatous character, as in the cases where bad results follow wounds received during dissections.

A gun-shot injury, whether it be in the shape of a wound from a bullet or cannon-ball, or from other missiles projected by explosion of gunpowder, usually combines several of the conditions above alluded to. There will be both contusion and laceration, and the velocity of the projectile may be such that it may merely bruise; possibly, however, it may tear its way through the tissues, or sever a part from the body, and sometimes the speed and force are such that the surface seems more as if it were cut instead of being lacerated. In these injuries there is greater likelihood of foreign materials, such as particles of powder, portions of wadding, of neighbouring objects, or of the person's dress, and the missiles themselves, being lodged in the body than in other examples.

The constitutional effects of a wound are usually in proportion to its magnitude, and so also is the danger, although both will depend greatly upon the nature of the parts injured. The violence may be such as to destroy life at once, or death may speedily ensue from loss of blood. Inflammation and its consequences may be productive of the worst results, and secondary hemorrhage from sloughing may endanger a fatal termination. The injurious effects may be of a primary or secondary character. In severe wounds it almost invariably happens that the system suffers from that state which surgeons have called shock or collapse. Some individuals are more susceptible of this than others; one party may be thrown into an alarming state of collapse from the sting of a wasp, while another may have his arm wrung off at the shoulder, and yet never suffer from this condition. It is characterised by great prostration, more or less insensibility, sickness, perhaps vomiting, cold clammy skin, small quick pulse—possibly it may be slower than usual, slow respiration, and (if the person can speak) feebleness of voice. This state usually supervenes immediately after the injury, and it is familiar to the surgeon after operations which he has himself performed, as well as after accidental injuries. In the course of a few hours reaction usually takes place; but some never rally, and death speedily ensues. If there has been much loss of blood, or if hemorrhage has gone on for hours, the danger is so much the greater.

The condition is usually treated in a satisfactory manner by cordials, and, if necessary, strong stimulants, although it occasionally
happens that such measures are of no avail. When the injury is to be treated as a wound, the surgeon may set about the appropriate method of dressing, even when the patient is in this state; in some cases it may be advantageous to do so, as with a luxation; but if a severe operation is requisite, such as the amputation of the limb, it is advisable to wait until reaction has come on, unless the additional injury thus inflicted should increase the collapse and add to the danger. From time to time the surgeon may see reason to depart from this general rule. I once saw my former colleague, Mr. Lizards, amputate in the thigh in an urgent case, when the collapse was extreme, yet the patient afterwards rallied under the continued use of the strongest stimuli, and made an excellent recovery.

Other features and circumstances connected with wounds, both of a primary and secondary character, will be frequently referred to in more appropriate parts of this volume, but this is perhaps the most fitting occasion to make some allusion to tetanus, which is a well-known and but too frequent result of such injuries. This disease is characterised by permanent spasm of the muscles of a portion or of nearly the whole of the frame. Its most common seat is in the muscles about the neck, throat, and jaws, and trismus is the word used to denote this particular case. In certain instances, the muscles on one side of the trunk are chiefly affected, and then the condition is termed pleurosthotonos; in other examples, those in front are involved, when the term emprosthotonos is used; and when the muscles on the back are in this state, the word opisthotonos denotes the peculiarity. Often most of the muscles of the body are more or less involved, and in these instances, as indeed in the others above named, the general term of tetanus is that commonly recognised by all practitioners. The spasm usually comes on in a very insidious manner. If the case be trismus, perhaps the first indication is a slight difficulty in swallowing and inability to open the mouth to its full extent. At this time, too, a slight hardness may be felt in the sterno-niastoid muscles, or in those of the nape of the neck. As the spasm increases, these symptoms become more conspicuous; the person cannot swallow or even admit solids within the range of the teeth; respiration becomes quick and irregular, and so does the pulse; the countenance becomes haggard, the features sharpened and pinched, and with the eye are expressive of great anxiety. Often a characteristic smile—\textit{risus sardonicus}—is present. Some patients may remain quiet in one particular attitude, while others are more restless. The spasm may relax slightly for a time, and then come again; in one instance, the disease will run its fatal course so rapidly that it is more like a prolonged convulsion than the true tetanic condition; in another the affection may continue many days ere it terminates, and the end may be a sudden or gradual remission of all the bad symptoms, though in general, so surely fatal is the malady, that, from the first, little or no hope can be entertained that the issue will be favourable.

The disease occasionally arises without any perceptible cause, and such instances are said to be idiopathic, but most frequently there is
apparent cause—a wound, sore, or ulcer; and when it is seemingly the result of some external violence it is called traumatic tetanus. It has been supposed that when a nerve is implicated, it is more likely to happen than if any other tissues were involved; but this, if true at all, does not always hold good; neither does the size of the wound influence the accession of the disease, for the most extensive wounds—incised, bruised, or lacerated,—will heal without any indication of the affection, while sometimes it is seen to follow the scratch of a pin.

The intractable nature of tetanus is such that the worst results are almost certain to happen, whatever course of treatment may be pursued. Almost every expedient, every medicinal resource, that ingenuity or skill could devise, has been tried, but in vain; for a remedy that has appeared to produce good effect in one instance, has totally failed in another under similar circumstances. At one time a depleting system has appeared to be of avail, while again a contrary treatment has seemingly acted beneficially. In one instance opiates have to all appearance been specific, and in another they have utterly failed. The warm bath, cold douche, division of parts near a wound or sore, even amputation, have all been tried, but the results have not been such as to encourage repetition of such methods of treatment. It would be ill-judged to persist in one mode of practice in such cases, when there was no indication of a favourable effect after a fair trial had been given. Some other measure—perhaps the reverse of that previously followed—should then be tried; and if at any time there was evidence of benefit from a particular medicine, then it should be persisted in so long as this good effect was evinced. The free use of purgatives by the mouth and as clysters, and then the use of opiates and antispasmodics, are the means which I should be most inclined to at first; and by narrowly watching the symptoms, some hint might be gleaned as to whether these should be persisted in or abandoned. In such cases as I have seen since the introduction of anaesthesia, that influence has seemed to me the most powerful for temporary benefit. I have never known chloroform fail to take off the spasms in the earlier stages of the disease. I have even seen patients use it, at their own discretion, with good effect; and my impression is that this, or any analogous agent, should be deemed one of the most powerful agents in mitigating the violence of this disease, and so possibly giving nature the opportunity of restoring the balance of nervous and muscular actions. Much in these cases must be left to the judgment and medicinal skill of the practitioner; and as the subject belongs almost as peculiarly to the physician as the surgeon, I shall not dwell longer upon it, but shall proceed to the consideration of other matters connected with wounds in which the rules of practice are of a more positive character.

Some wounds are so extensive, so complicated, so peculiar, and so hazardous to life, if the injured part is allowed to remain on the body, that amputation is the proper course of proceeding; severe compound fractures and dislocations, extensive gun-shot injuries, lacerations by machinery, and other such examples, often demand this operation: in which event, the wound left on the body, though perhaps comparatively
of great size, is always supposed to be of a less formidable character. It is in the condition of a simple incised wound, which is the most favourable of all that the surgeon has to deal with. Such are the wounds which he himself usually inflicts in the performance of cutting operations; but as the use of the knife forms so small a share of the treatment of any injury or disease,—being, perhaps, the work of a few seconds or minutes only, whilst the after-practice may last for weeks or months,—it is highly incumbent on the young surgeon to study the science and art of treating and dressing such injuries.

Whether a wound be punctured, contused, lacerated, poisoned, or gun-shot, it is usually a good object to bring it as nearly into the condition of a simple incised one as circumstances will permit. It is evident that this cannot be effected in all these instances; nevertheless, much may be done by a judicious practitioner to forward this object. Thus, in a puncture, a portion of the sharp point with which it has been inflicted, may have been left in the part, and, if this were allowed to remain, it would be almost certain to retard the cure. Again, in contusions and lacerations, there may be great effusion of blood in the surrounding tissues, or there may be foreign substances driven into them. In poisoned wounds there is a peculiar source of irritation, and in those termed gun-shot, if foreign bodies remain in contact with the textures, the result is almost invariably more troublesome than when the track is left comparatively clear.

Sometimes it is improper, or impossible, to remove foreign materials at the commencement of treatment. In gun-shot injury, for instance, a large portion of the wound may be deprived of life, and can only separate by sloughing; or the most skilful surgeon may not be able to remove a foreign body which may be in the part. Then, in effusions of blood, it would in general be improper to make an incision for its escape: this should be done only when it has become evident that it is a source of irritation, and that it is not likely to be absorbed. In sprains and slight contusions, the eechymosis (or, in other words, the effusion of blood) invariably disappears. In simple fractures and dislocations the extravasation is always absorbed in the progress of time, as it is also in the instance of thrombus, which occurs during venesection, when the orifice in the skin is not kept directly over that in the vein.

Inflammation is, in my opinion, the inevitable consequence of all wounds, however trivial, or whatever their magnitude. Sometimes the action following a puncture with a needle or a lancet is so imperceptible,—the ordinary symptoms of inflammation being scarcely appreciable, that some have disputed this point. In a wound healing by the first intention,—that in venesection, for instance,—the process which Hunter named "adhesive inflammation," has been asserted by John Bell, Macartney, and others, to be different from that of inflammation. The difference, however, seems to me to be more in degree than in quality. Adhesive inflammation is, perhaps, the mildest of all forms of this disease, and the nearer the approach to it in a case
of wound, so much the better it is, in general, for the success of the treatment. The immediate removal of every cause of irritation, in so far as this may be possible, is, therefore, an excellent rule of practice. Some foreign substances, which must of necessity be left, as ligatures and stitches, are known to produce a very small additional amount of irritation, which is, however, amply compensated for by their own merits; but in the case of a poisoned wound, such as the bite of a poisonous snake, or of a rabid dog, where the mysterious influence of the agent is too often ungovernable, the surgeon cannot too speedily resort to such measures as may destroy the poison ere it enters the system. Hence the advantage of an early application of suction, the caustic, cautery, or even excision of the bitten part. But as some of these doctrines are more fully illustrated elsewhere, I need not dwell on generalities here.

In some incised wounds, and, indeed, in all of any other kind, with but few exceptions, the chief object to be kept in view is to procure union by the first intention. To forward this desirable occurrence, the wound must be cleared as completely as possible of all extraneous matter. A soft sponge and water must be used, to wipe away blood and every other material likely to prevent the surfaces coming accurately in contact. Such a number of ligatures having been applied as may be thought advisable, in the manner, and according to the views already described, their ends being left out at some convenient part of the wound, the surfaces must be carefully approximated, and held together by means of stitches, straps, and bandages, as may be deemed most convenient. When ligatures are left in a wound, of course union cannot occur where they are placed; but in general, as soon as they are detached, the spaces or sinuses through which they have passed speedily heal. If all circumstances are favourable, union may occur throughout the whole track (saving where the ligatures are) in the course of twenty-four hours or less; and in eight-and-forty hours, or on the third day, when it may be thought advisable to remove the stitches and first dressings, the bond will be tolerably firm, but certainly seldom such as to save the necessity for further support. In some cases, when there is no drag on the parts, and, consequently, no disposition to separation (as in the wound of venesection), a bandage is not requisite after the first four-and-twenty hours; but when the wound is considerably larger, and the edges heavier, a further degree of support is demanded, else the tender adhesions will be likely to give way.

In most instances, when it is said that union by the first intention has occurred, there is usually some little point on the surface where it does not happen (as where the threads hang out), and that same point will seldom heal under the lapse of three or four weeks: but this need not be considered a drawback, for there are few instances where a wound can be exposed to the least violence within that period; in a stump, for example, whether of the finger or of the thigh, where early union may have taken place, no freedom can be
taken with it,—no artificial limb can be applied for weeks, ay, even for months, in consequence of the tenderness of the parts; and here, then, it really signifies less than some seem to imagine, when a small portion of the wound remains open for three or for six weeks. In stating this, I by no means wish the young practitioner to suppose that he should be careless on such a matter; but it may be satisfactory for him to know, that when surgeons talk of union by the first intention having occurred throughout a wound, such little troublesome points often remain, which the most consummate skill cannot cause to heal until nature seems inclined, and this will not be until the open part has gone through the process of suppuration and reached that of healthy granulation when the sore will cicatrize, as it were, spontaneously.

The above remarks apply only to such wounds as have had their surfaces open to the atmosphere. When these are left exposed, it is impossible that union of this kind can occur; and in external wounds, it only happens in those instances where the surfaces have been so accurately approximated by the surgeon that the air has been excluded. If this be not done, suppuration is the inevitable result: on the contrary, if the surfaces have never been exposed, the most severe wounds will often unite without the occurrence of suppuration;—as those of the soft parts in simple dislocations and fractures, where the union, though in some respects different from that usually spoken of as by the first intention, is, nevertheless, in most features remarkably similar.

But the best examples which I can give of the favourable union of parts, are those which have been afforded in modern times by the operations termed "subcutaneous." When Lorenz, Sartorius, and Delpech, divided the tendo Achillis for club-foot, a large opening was made in the skin, and the tendon was freely exposed to the air, but the wound, healed so slowly that the operation was deemed of little value, until Stromeyer showed the advantages of the subcutaneous incision. Since then, extensive use of the knife has been made, so as to divide broad tendons and muscles (the latissimus dorsi, for example, the deltoid, and the rhomboideus major); but the instrument has been so narrow, and has caused such a small puncture in the skin, that air has not been admitted, and the whole track has united without a single unpleasant symptom. One object in such cases has been to permit the retraction of the divided ends: the parts cut, therefore, cannot be said to have united by the first intention, but the whole gap left between the retracted extremities has done so: at all events, there has been no suppuration, nor has there been any granulation, in the ordinary acceptation of that term.

Whether a wound is, or has been, exposed to the air or not, I deem it essential to the process of immediate union, that the parts be kept in perfect quietude. If the surfaces are allowed to rub upon each other in the least degree, the process is certain to be prevented: in which case, the wound can only heal by suppuration and
granulation. The only exception to this general rule which I deem worthy of notice, is in the instance of simple fracture, when, after the lapse of six or eight weeks, the ends of the fragments have not united: in such a case, a little motion may really be of service to induce that excitement which seems to be wanting: but even here, perhaps, after new action has thus been produced, perfect quietude is again necessary to allow the healing process to go on favourably.

If a wound does not close in the manner above referred to, it must do so by suppuration, granulation, and cicatrization, and ought to be treated according to the methods afterwards recommended for these processes. When immediate union is not expected, the best plan is to foment and poultice to encourage suppuration; for, as is afterwards stated in the chapter on effusion of pus, I believe that this event will, in some degree, alleviate the patient's sufferings. Possibly there may be such a degree of inflammation as to render leeches advisable: sometimes it may be of a gangrenous character: often it is erysipelatous—as in severe punctured wounds, or those received in dissections, when high action ensues; but the directions given in future chapters, for the treatment of these different conditions, saves reference to them in this place.

When bleeding from a wound has been staunched, and all extraneous material has been removed, its edges are generally brought in contact, in hopes that they will speedily unite. Various means are resorted to for keeping the cut surfaces in apposition, and these characterise the different kinds of sutures. A combination of stitching and bandaging is applied, in almost all instances where a wound is of such magnitude that its edges gape.

The interrupted suture (fig. 52) is in most frequent use. It is formed by passing a needle and thread, such as are represented on page 34, through the skin and subcutaneous cellular texture from without inwards on the one side, and from within outwards on the other, at about the fourth of an inch distant from each margin, and fastening the ends of the thread with sufficient tightness to prevent the surfaces from separating. It has been recommended that the knot should be kept at one side, instead of being left exactly over the wound as is the usual custom. The stitches are proportioned in number to the extent of the wound; they are commonly placed about an inch from each other: where the distance is greater, the parts may be supported by a few straps of adhesive plaster, placed between each stitch, thus (fig. 53), or as represented in the next cut (fig. 54), where it will be observed the strap is in one piece, with open spaces in it to permit the application of lotions or ointments, or the free discharge of matter; and, over all, it is usual to apply a por-
tion of lint wet or dry, or spread with simple cerate and a few turns of a roller, which gives a more uniform support to the whole parts, and thus prevents any dragging on the stitches, from a tendency of the edges of the wound to fall asunder. In a large wound,—a stump, for example,—the roller can seldom be dispensed with.

Some object to stitches in the dressing of wounds, on the ground of the additional pain and irritation they occasion; but I am firmly convinced, from experience, that the pain is amply compensated for by the security they give, and the irritation seems to me considerably less than that caused by the farrago of straps and bandages often employed instead.

During an experience of forty years, I have had ample experience of stitches, and I cannot remember a single instance where they seemed to have been productive of harm;

on the contrary, I have often observed their remarkable efficacy. If they are employed in improper cases, they may do harm, but the injury then ought to be attributed to the want of surgical skill which has led to their use or abuse, and not to the means themselves. Thus, sometimes a surgeon foolishly endeavours to drag the edges of a wound together by means of stitches, when the gap is really so great, and the surrounding parts are so unyielding, that approximation cannot be accomplished without much force, which produces great pain, and, moreover, is certain to bring on speedy ulceration in the site of each thread. Occasionally, when the stitches seem to produce little or no irritation, they should not be meddled with for the first three or four days, but, in many instances, it is doubtful if they are of much service after the first eight-and-forty hours; they are generally, therefore, removed on the second or third day from their introduction, but there need be no fixed rule for the practice, as the surgeon should allow himself to be guided by circumstances, and use his own discretion as to the proper
period; indeed, within these few years so much have I become impressed with the advantage of stitches, more especially in the treatment of stumps and large cutaneous wounds, that I frequently permit them to remain until detached from one side of the newly-formed cicatrix by ulceration. When they are to be removed, the knot should be seized with the dissecting forceps, gently turned aside, and the point of one blade of the surgical scissors insinuated under the thread, which should then be divided, and withdrawn through one of the apertures. The method of treating a wound by means of stitches, for the purpose of encouraging early union, will be further illustrated in describing the treatment of stumps immediately after amputation, and in various other ways, as in the descriptions of the operations for hare-lip and cleft palate.

In many instances a bandage is not at all necessary when stitches have been applied; and wherever it can be dispensed with, it will be better to do so, as, in my opinion, the dressing upon a wound intended to heal by immediate union, cannot be too light and simple, but whenever from the shape or weight of the parts there is a risk that they may fall asunder, the bandage had best be used.

A small bit of lint covered with some simple ointment may be laid along the surface over the stitches; or the lint may be moistened with water and covered with oiled silk; but even these may, in most instances, be dispensed with. Occasionally it is of seeming advantage to keep the surface cool and moist, with a continued small stream of cold or iced water, which may be made to trickle along a bandage or strip of lint, having one end in a basin close at hand, and the other over the wound or dressings.

The twisted suture (fig. 55) is often applied with great advantage in instances when it is required to keep the parts very steady, and in particular when some considerable stretching of the neighbouring textures is necessary; as, for example, in the operation for hare-lip. In some cases of this malformation, the interrupted suture will serve to keep the cut surfaces of the lip together; but, in general, the drag upon the threads would be so great in the seat of each stitch, that ulceration would be almost certain to come on; and supposing the edges of the wound did not separate, much pain and trouble, to say nothing of the unseemly sears that would follow, would be the inevitable result. The twisted suture is, therefore, highly advisable in all such instances; and considering the extent of parts kept steady by the needle and thread, it seems impossible to retain surfaces in contact, on the living body, in a more simple and efficient manner, especially if conjoined with an apparatus for pushing the parts towards each other, which will be referred to when the subject of hare-lip is discussed.

This kind of suture is made by passing a common sewing needle through the skin and other textures, from one side of the wound to
the other, and twisting a thread over each end of it, as represented above, with such a degree of tightness as to keep the surfaces in contact. When two or three needles are used, it may be an additional security to carry the thread, as often as may seem advisable, from one to the other, in the way represented in the sketch; and in all instances each needle must be passed sufficiently deep to prevent any part of the wound being open behind, as sometimes happens in the lip, where, besides, the labial arteries may still continue to bleed from the surface thus improperly left. After the thread has been applied, the point of each needle should then be cut off with a pair of common pliers (fig. 56), similar to those represented here. Various kinds of instruments have been recommended for this purpose, but I have found none so convenient, either as to efficiency or price, as those used by the workers in wire. Besides the point, the round end of the needle is occasionally cut off; but I often prefer leaving it on, as it is less likely to catch upon anything, such as the patient's clothes, than when cut.

Needles with steel points (fig. 57), which can be screwed off and on at pleasure, have been recommended and used for the above purpose, and they have been made of gold or silver under the absurd idea that these precious metals are less irritating to the parts than the baser metals. The polished surface of the common Whitechapel sewing needle, is as little likely to do harm as that of either of the other metals; it possesses greater proportional strength, and its size is likely to produce less pain and irritation than the more clumsy instrument above referred to. A needle of this size (fig. 58),

with the eye and end covered with a bit of glass or scaling-wax, to enable the surgeon to push it through the textures, will answer for general purposes. It is such as is recommended by John Bell, with the addition of the round head, whereby the surgeon can dispense with any assistance from the port-aiguille, or the handle of a tambouring needle. For many years I have used a needle made expressly for the twisted suture. It is flat and sharp at the point, and makes its way more readily than the common needle; it is, moreover, not so highly tempered, and its point can therefore be more readily snipped off with the pliers, whose edges will always suffer from the hardness of the former.
SUTURES.

53

I now rarely use any other needle for the twisted suture, and having succeeded in getting a glass head put on by the makers, I consider it admirably fitted for the objects in view. Figure 59 represents the needle in its full size, and also the shape of the point. The experience

Fig. 50.

Fig. 60.

of many years has fully confirmed my early impressions regarding this needle, but of late years I have often used a needle of the same shape with a bend at the end, as seen in fig. 60, which is perhaps an improvement on the glass bead, as the latter is liable to break.

The thread for sutures should be much the same as that for tying arteries. For the common stitch nothing answers better than ordinary linen or silk thread doubled, but I prefer a thick soft substance for the twisted suture; and with either of these, as also with the ligatures for arteries, if the material appears too limber, a little bees-wax on the surface may be advantageously used to prevent entanglement, and to facilitate the casting of the noose as already explained at p. 29.

In consequence of the recommendation of Mr. Numneley, I have occasionally used caoutchouc thread for the interrupted suture; but after giving it repeated trials, it seems to me, for various reasons, inferior to the common silk or linen thread. It is more difficult to procure; the slightest stretching causes it to extend irregularly; it becomes thin at one part and thick at another; it curls up into knots, and is not so readily fastened as the common thread; and when I add, that it does not seem to produce less irritation than that for which it has been substituted, and is, besides, somewhat more troublesome to remove, I think that sufficient grounds have been given for the opinion above expressed.

Other sutures are described by surgical authors, but they are seldom used in practice: and, so far as my experience goes, I am inclined to think that with either of the above, slightly modified by circumstances, all the desired objects of the suture can be obtained. In certain parts of the body, as in the female perineum, a straight needle can scarcely be passed so as to penetrate deeply; but one of a curved form, such as may be seen at p. 34, can be used either for the interrupted or twisted suture. In deep wounds, or such as are liable to movement with the chance of displacement, the quilled suture (fig. 61) may be used with confidence. The sketch shows its principal features. A common needle, carrying a stout double thread, is passed deep into one side of the wound, at a dis-

Fig. 61.
SUTURES.

tance of half an inch or more from its cutaneous margin, and out at the other at a similar distance. The thread being cut at the needle, so that the latter may be taken away, a knot can be made by tying the two ends together; a quill or bit of bougie should then be put between the threads, when, by drawing them in a back-ward direction, the quill will be brought close down on the skin. A bit of quill or bougie may now be put between the threads where the needle was first introduced, when, by casting a noose, and finally a knot, a sufficient tightness can be given to close all the principal parts of the wound. Should the surface gape, one, two, or three interrupted sutures may be placed on the margin of the skin.

In the twisted suture the needles should generally be removed on the second or third day. Removing them earlier might be attended with danger of the wound opening; and leaving them longer might cause such irritation as to produce a similar result. In some persons, however, they occasion little or no evil when permitted to remain; and I have frequently allowed four, five, and even eight days to elapse without interfering with them at all. In removing these sutures, the knob or end should be seized betwixt the fore-finger and thumb, or by the forceps, and with a gentle twirling motion the needle should be withdrawn. If a common sewing needle has been used, it must be withdrawn through the course in which it has been pushed; but if it be such as one of those represented on page 53, and the top has been cut off, it may be withdrawn in the direction most convenient to the surgeon. The threads may possibly remain, and as they may still give some support, but cannot produce any harm, they had better be allowed to drop away of their own accord; indeed, in order to keep them on a day or two longer, when this is thought desirable, I am in the habit of covering the thread and adjacent skin with a film of collodion, either at the time of the operation or now, which is very useful for this purpose. It is scarcely necessary to state that the parts should be kept as steady as possible whilst these proceedings are going on. The withdrawal of the needle is apt to be attended with a sudden jerk, and care should be taken to avoid it, by also keeping a steady command over this instrument.

After the removal of any kind of suture, although the surfaces of the wound may have united, it is good practice, in general, to re-apply straps and bandages, so as to give support to the tender adhesions, and underneath these or between the straps and bandage, a bit of lint, dry or moistened with water, or covered with simple cerate, may be placed. Sometimes straps alone will suffice; at other times a bandage may seem best: commonly both at once will be found most efficient. If the wound has not united, a variety of dressings may be required, as will be noticed in the chapters on suppuration and granulation; and here I may refer to my remarks on dressing stumps and various kinds of wounds, for further illustrations of this department of practical surgery.
CHAPTER V.

LANCET. CUPPING. LEECHES. COUNTER-IRRITANTS. CAUSTICS. CAUTERIES. ISSUES. SETONS.

Some notice of certain means of practice and minor operations (as they are usually called) may be more conveniently introduced here than at any other part of this work. Besides the cutting instruments already referred to, the lancet (fig. 62) is indispensable in general practice, for although its use has in a great measure been superseded, it is undoubtedly more applicable to certain proceedings than any other sharp-edged instrument. The manner of holding it is exhibited on another page, where it is represented as applied to its most legitimate purpose, that of opening a vein at the elbow. It may still, however, be considered the fittest instrument for sundry other operations, as in making the slight scratch on the skin in vaccination, in opening small superficial abscesses, such as the pimple and boil, or in puncturing vesicles, although for the latter purpose a common pin will answer equally well. Sometimes the lancet is used to divide small vessels near the surface. In certain forms of inflammation of the eye, for example, it is more efficient than any other cutting instrument, chiefly, perhaps, in consequence of the fineness of its edge. It may be used to divide certain enlarged vessels, such as are so frequently seen in chronic conjunctivitis, or in the acute forms of the disease, when this membrane becomes infiltrated with serum and blood. In other instances the lancet is used for the purpose of opening the skin, in great tension of that texture from effusion of serum, as in anasarca, and also in the oedema resulting from crysipelas or inflammation. The scalpel, or bistoury, is often used in these cases; but many practitioners object to long incisions, more particularly in anasarca, and as the lancet makes openings sufficiently large for the purposes in view, they give it the preference. For all these proceedings the instrument is held between the thumb and fore-finger, as afterwards represented, the position of the hand being occasionally varied according to circumstances. Sometimes the point is merely thrust in, so as to make a puncture, when it is withdrawn immediately, whilst at other times it is carried along, so as to make a wound of some length; but for the latter purpose it is certainly less efficient than a blade of more substantial size. Formerly a larger lancet was generally preferred for opening abscesses near the
surface; but I can scarcely say that I have seen one of the kind for the last thirty years, the scalpel, bistoury, or a blade constructed expressly for the purpose, represented in the chapter on abscess, having been always used instead.

When the lancet is chosen for the purpose of abstracting blood, it is usually in instances where a large vein, or an artery, such as the temporal, is to be opened; but, by making, with such an instrument, a variety of punctures in the skin, a considerable quantity may be allowed to escape, especially if means are used to promote its flow. Such means are found in the various forms of cupping apparatus. Instead of a single lancet, held between the finger and thumb, being used to make the punctures, a number of blades, six, nine, or twelve, are placed in a brass case, and so connected with springs, that by proper management, the whole of them may be carried through the surface in an instant, with a rapidity as quick as the motion induced by the main-spring of a gun-lock; and then, to promote the flow of blood, an exhausted receiver is placed over the wounds. The latter is commonly made of glass, and various shapes and sizes have been recommended and used. The air has been exhausted in a variety of ways, too, as by the mouth, for example, the most ancient and natural of all, applied either directly to the wound, or to an opening in the upper end of the receiver: a syringe has been used for the same purpose, or another receiver, from which the air has been already pumped out, has been placed over the cup covering the wound; but the flame of a spirit-lamp seems most in service with those who practise this operation. Recently an ingenious instrument of the above kind has been recommended to enact the part of a single or any number of leeches. A little wound is made on the skin, in the shape of a leech bite, with a peculiarly shaped blade, which is guided by a spring, and over this wound a small glass tube is placed, from which the air is withdrawn by the spontaneous action of a spring. The single opening on the skin, and the similar amount of blood that might be drawn by a leech, have induced the appellation of "the artificial leech" to this instrument, and when living animals cannot be had, such an apparatus may be of service in the surgeon's hands. The cutting part of this instrument can be applied as often as desirable, and with a variety of tubes the action of any reasonable number of leeches might be secured with as much certainty as if the animals themselves had been employed.

There are few instances in which local blood-letting is required where cupping will not be found applicable; but in some the lancet only can be used, or else leeches; and there are certain cases where these seem the most applicable. On the hands or feet, the gums, the cervix uteri, or on hemorrhoidal tumours, leeches are usually deemed more advisable than the lancet. A variety of circumstances may dictate the preference of one of these methods over the other, for abstracting blood locally; but I need not point out what common sense and observation may render apparent; for the sake of illustration, however, I may state that on the face the lancets might leave unseemly
LEECHEES.

...scars, and, in addition, the glasses could not be advantageously applied, owing to the irregularity of the surface. Here, therefore, leeches are to be preferred, as in the case of ophthalmia, when they are set on the eyelids, or possibly "the artificial leech" above alluded to might be called into service.

When these remarks were first written, both lancet and cupping apparatus were fast going out of use, and now in 1870 they are nearly as little known among the rising generation as if they had never been in association with the profession. At this period scarcely a candidate for a diploma at the College of Surgeons has seen one or other used, and time alone can show if they will ever again be in favour.

I know of no objection to leeches on any part of the body under circumstances requiring local depletion, excepting such as reason might dictate; yet the latter seems with some to admit of most unbounded liberties, for I have known a person allow a leech to fasten on the cornea, in an instance where the surgeon had ordered a number to be applied to the eyelids. To those who know that the wound inflicted by the bite of this animal would be certain to occasion opacity of this transparent part (and what tyro in the profession can be ignorant of the likely result of such an injury?), it may appear supererogatory to advise that the bite of the leech be limited to the skin, or at most, to the mucous membrane of the eyelids, or that covering the sclerotic; but the mistake above alluded to, must, with them, plead my excuse for offering an advice to others who may be less familiar with such matters. With this exception, and the still more apparent one of not placing these animals on such parts as may enable them to crawl out of sight into any of the cavities, or into recent open wounds, as is said to have happened, I know of no instance where they may not be applied. In contusions or sprains, where they are put on the healthy skin, a little blush of erythema may supervene; there will be slight swelling and pain, and possibly a little mental alarm, but the threatened mischief will usually pass away in a few days at most. I have used them extensively on the raw surface of ulcers, and also on parts affected with erysipelas, and have never had cause to impute harm from their application: in the former case I have had much reason to be satisfied with their services; and in the latter, I have never seen a single example where mortification or any other serious affection of the bitten part could be attributed to the injury of the leech bite.

The necessity for diligent fomentation after the use of lancets, or the application of leeches, ought not to be forgotten, nor should the difficulty of arresting the bleeding from the bites of the animal be overlooked. In the adult it can scarcely be imagined that prolonged bleeding from one or more of these wounds can ever be productive of harm; but in an infant, after a leech has been applied, there may be danger; or, at all events, the continued oozing may be a source of much alarm to the parents and attendants: in such a case, if any ordinary astringent, such as cold air, cold water, solutions of alcohol, sulphate of alum, zinc, or copper, leaves or tincture of matico, per-
chloride of iron, strong acids, lunar caustic, or other astringents, will not check the flow of blood, a fine needle may be thrust across the skin in the seat of the wound, a small pad of lint placed on the open surface, and a thread tied over, as in making the twisted suture (p. 51), will effectually stem the flow: indeed, I believe that this plan will be productive of less pain to the little patient than most of the agents above referred to.

The various methods of producing counter-irritation are well worthy of notice here. Perhaps the simplest of all is that of hand-rubbing, with the bare palm, or with a little olive oil. A more stimulating fluid in the shape of a liniment or soft ointment, may be used, or the hand may conduct a dry towel or flesh-brush. But practice of this kind is in such common use among the non-initiated, that I need not do more than allude to it here, although I am inclined to think, that frictions and manipulations are less resorted to in the practice of surgery than they really deserve. Perhaps these means may scarcely be deemed worthy of being held as counter-irritants; yet, in some instances, I believe they are so, whilst in others they seem to be direct stimulants, either by inducing nervous or muscular action, or an increase in vascular excitement, whether arterial or absorbent.

I can fancy, too, that pressure may have some effect in softening secretions and chronic deposits. I once came unexpectedly upon a charlatan, in the exercise of his avocations, who was noted for curing chronic swellings, and found him busy applying some force to the swollen part by means of a common tourniquet (fig. 33), which he had applied round the limb, and which he tightened and relaxed at will. This, I had reason to believe, was his chief method of treatment in cases of this kind.

Dry cupping may be a source of considerable counter-irritation, and the practice is, in my opinion, far less resorted to, among modern surgeons, than it deserves to be. The method of dry cupping consists in using receivers, or glasses, and exhausting the air from them before or after they are placed over any particular part. The increase of blood in the part within the vacuum seems, in some instances, to produce as good an effect as a blister, or even a more severe form of counter-irritant, such as the caustic or cautery; indeed I have in some instances perceived more benefit from the dry cupping than from any such severe measures. In certain cases of deep-seated pain in the spine, in the hip, or in the knee, I have known the practice to be attended with vast benefit; and, although it ought not to be considered an infallible remedy, I do not hesitate to speak highly in its favour.

Amongst the various ointments which have been used as counter-irritants, I know of none which has been so much in repute, or which possesses such powerful influence on the skin, as that formed by a combination of a drachm of tartar emetic with an ounce of spermaceti ointment. Sometimes it is made with a smaller proportion of the salt, and it seldom fails, when rubbed on the skin night and morning, to produce a crop of pustules, which cannot but be of service, if counter-irritation is likely to be of any avail at all. Sinapisms and blisters
need no particular comments here: the former I believe to be, if properly made and applied, nearly as powerful as the latter, and the modern preparation of cantharides, in the shape of blistering fluids and papers, may be deemed great improvements on the older ointments and plasters. In warm climates, and in all diseases when it is of consequence to induce vesication rapidly, these latter means, which produce their effects in the course of three or four hours, may be resorted to with great advantage. It should not be forgotten that if these irritants be often repeated, they may actually destroy the vitality of the surface; thus small sloughs are by no means uncommon where the tartar emetic ointment has been used, and extensive mortification of the skin has been known to follow the application of a blister. In children this is more likely to happen than in the adult; and I have known death to be the result of such an occurrence.

The linimentum iodi of the British Pharmacopoeia answers as a strong counter-irritant, and some consider that the nitrate of silver, rubbed freely over the cuticle, produces a stronger effect than cantharides; but when it is desirable to cause a more sure degree of counter-irritation than can be produced by the means above referred to, the caustic potash may be applied with advantage. This preparation is generally used thus: a slip of adhesive plaster is placed over the skin, having a hole in its centre, perhaps an inch long and half an inch broad, or of such other size and shape as may be deemed advisable: this hole being placed opposite or over the deep-seated pain, a bit of the stick of caustic, moistened with water, is rubbed on the surface until it assumes a greyish colour, and the opening seems filled with the caustic in a fluid state, when another piece of plaster, without any hole in it, is placed above that already present, and over all a poultice may be applied immediately. In a few hours the pain will be excessive: a portion of the skin will be killed by the caustic, and converted into a slough, which will separate in the course of time, under the use of poultices and other measures to be afterwards taken notice of. Occasionally, instead of rubbing on the stick of caustic, a portion of the size of a pea is placed on the skin, and allowed to deliquescce slowly, being retained there by a piece of plaster put over it.

Instead of the potash some resort to actual fire as a counter-irritant, and the moxa is then put into requisition. The moxa may be made of any material which will burn readily; but perhaps the most convenient will be a little cotton, or bit of surgeons' lint, which has been previously dipped in a weak solution of nitrate of potash, well dried, and then stuffed into a small pill-box, with both its ends open. The box should be held over the part about to be burnt, by means of a piece of wire twisted round it, or a kind of forceps made for the purpose, and, after ignition, the combustion should be kept up by means of a long blow-pipe, or a pair of bellows. The moxa is sometimes merely held over the skin so as to excite a glow, but more frequently the ignited material is held close upon the surface so as to destroy its vitality at once. When the substance is nearly burnt out, the patient, unless chloroform be used, experiences acute pain, and the
skin may be observed to shrivel and become brown under the intense heat. At the end of the process, a fold of lint, moistened with cold water, should be applied, and in the course of an hour or two should be succeeded by a poultice. Instead of applying heat in this way, some prefer to cauterize with the heated iron, thus producing death of the part touched with the metal, in a more rapid manner than with the moxa, and of these three modes of counter-irritation, I give a decided preference to the heated metal. The caustic potash (the potential cautery, as it was usually termed) produces its effects far more slowly, and with less certainty, than either of the other two, being in some instances apt to go deeper than might be wished, or to spread too extensively over the surface; and it is chiefly on the latter account that the plaster with the hole in it is recommended as a preventive. My old colleague in the Royal Infirmary of Edinburgh, Mr. Lizars, used the potash extensively, and the expression of pain heard in his wards a few hours after his visit, bore ample testimony to the distress which it produced: I have myself used it frequently, and my impression is still the same regarding it. The moxa is troublesome to apply effectively; and often, after the patient has been put to a deal of pain, its results on the surface are so limited that the counter-irritation is slight indeed. The moxa, in my opinion, produces much more acute pain than the caustic, and possesses no advantage over it that I am aware of. At one time I used this remedy frequently, but for the reasons above stated I have latterly almost given it up; and now, when such an agent seems requisite, I generally resort to the heated iron,—the actual cautery, as it is usually termed, in contra-distinction to the potential, the same term being commonly given to the moxa also.

The horrors and cruelties attending the use of the heated iron in former times afforded too good reason for the neglect with which it was subsequently treated; and it cannot be thought wonderful that when men high in the profession disputed about the superiority of gold or iron as a cautery, about the size and shape of the instruments, and also the smallest number with which it was possible to practise surgery; and when, moreover, it was the custom to apply it in every disease to which the human frame is liable, the character of the profession suffered, and as it fell in public estimation, so did that of the once "powerful sceptre,"—the actual cautery. Though there are still many prejudices against it, and certainly many just objections to its indiscriminate use, it seems to be more in vogue among modern surgeons than it once was; and, under judicious guidance, it appears to be a more manageable, equally efficient, and less painful counter-irritant than either of those last mentioned. It is, besides, highly serviceable in arresting hemorrhage, when, perhaps, no other means will answer, and is altogether of much use in the practice of surgery. It must be confessed, however, that there is an appearance of rudeness and cruelty in its application, which renders its frequent use objectionable in modern practice.

In continental hospitals surgeons often take greater liberties with
Cauteries.

61

to their patients than is the custom in this country, and the cautery seems in more general use with them than with us. Many persons imagine that we need be less nice about the feelings of patients in hospitals than of those in private practice; but with reference to the cautery, I see no reason why this should be so; and as it will seldom happen that a person, whatever his circumstances in life may be, will anticipate with calmness the idea of the contact of heated iron, and will not prefer what he is led to consider a milder and less painful application, the opportunities for using it are probably not so frequent as its utility deserves. The effect which the seeming cruelty has upon the neighbouring patients in an hospital, and the character for rudeness which the surgeon who persists in using it frequently may acquire, often cause it to be dispensed with, even among its most strenuous advocates; yet one cannot but hold in contempt that so-called "amiable sensitiveness" of the practitioner, who, whilst he objects to the application of the heated iron, because it is used upon horses, and because, too, it is a coarse, vulgar, and seemingly unscientific remedy, will practise a wilful imposition by means of caustics, which do their painful work after he has left the house. Such a person is one of those "amiable" beings, too, who will open an abscess by the repeated application of the caustic potash, because, forsooth! the use of a knife is a painful expedient, although, in reality, the pain of the latter, however acute it may be, is probably not greater at any moment, nor does it continue for a hundredth part of the time of the other. Much of the force of these observations has been modified or set aside by the modern practice of anaesthesia either local or constitutional.

Various shapes and sizes of cautery will be found of service. Thus, if it be desired to touch merely a small point,—as the orifice of a bleeding vessel,—a bit of wire will suffice, or there may be a small bulb at the end of a fine rod of iron; but when a large surface requires to be seared, a ball of metal the size of a boy's marble or of a walnut may be necessary. Sometimes a large flat surface is best, whilst on other occasions a narrow edge may be thought most desirable.

In certain hemorrhages, as when a vessel has run in a bone, I have seen the cautery effectual; but it is seldom required for the suppression of bleeding.

The application of the cautery to promote the contraction of sinuses, fistulas, and abnormal orifices, may be, in certain cases, strongly recommended, and a great reliance should be placed upon it as a counter-irritant. For the latter object, instead of applying a ball or single mass of iron, so as to cause a slough an inch or more in length, and perhaps hal the breadth, I generally bring a larger extent of surface under its influence, by scoring the skin much in the same way as the operation of firing is done in the horse. The process is slower, and therefore more painful (if chloroform be not used) than a single touch of the instrument; but in some causes it presents such advantages, in my opinion, that, when the cautery is actually appealed to, the difference may be overlooked. I was first led to apply it in this
CAUTERIES.

way, from drawing some analogy between certain nodes on the tibia and splints on the young horse. In such instances, it is well known that when the animal continues lame for a length of time, and when stimulating ointments and blisters have seemingly been used in vain, the application of the cautery effects a cure, particularly if due rest is given afterwards. Although in most instances a painful node requires constitutional treatment as well as local, and differs in almost all respects from what is termed a splint in the lower animal, yet occasionally such chronic swellings are met with on the surface of the tibia, which have resisted all the ordinary modes of treatment, internal as well as external. Many years ago a case of this kind occurred in my practice. A young man, aged twenty-three, had two years before contracted syphilis, and after the primary symptoms were cured, a node formed on the tibia, which occasioned him much distress:—from being a person of stout appearance, he now seemed like one exhausted by a painful and malignant disease. Before I saw him he had undergone various courses of mercury and other medicines, and had the part repeatedly leached and blistered. He was again subjected to similar practice, and also tried iodine freely, both internally and externally, but with no mitigation of his sufferings. Rest seemed to produce as little benefit, and his disease was worse at night. For six months the progress of the case was carefully watched, when the cautery was applied in the mode referred to, and such as is here represented by these lines (fig. 63), each being about half an inch from the other. During the evening after he slept better than he had done for three months before, and from that time his disease was cured. I saw him occasionally for years after, and he had never subsequently experienced another twinge of pain in the swelling. I have had similar success in other examples; and, though I do not predict or anticipate invariable success from the measure, I recommend it strongly in such-like instances, especially where the affection seems to be, and perhaps is, entirely local.

The following cut (fig. 64) exhibits the shape of the instrument I use on these occasions. It will be observed that it is similar to the cautering iron of the veterinary surgeon. The convex edge is about one inch and a quarter in length; but when it is desirable to cover an extensive surface, as in spinal or hip disease, one of larger dimensions may be selected, although such as that alluded to will suffice for general purposes.

The two heads of the cauteries here represented (fig. 65) are such as are most generally in use among surgeons: the round head for
making large eschars, the pointed one for touching the surface less extensively. Sometimes the instrument is made of a flat button-shape, at other times quadrilateral; but there can scarcely be a limit to shapes and sizes of such tools, for I have known the most cautious of surgeons, an advocate for the cautery, use almost every shape and size, from a wire—such as the stilet of a bougie, or a steel bougie itself—to an ordinary fire-poker.

The iron should be heated to a dark red, and its margin, after having been rubbed clean on the hearth-stone, floor, or bit of wood, should then be drawn along the skin in one or more lines, or as indicated in fig. 63, the lines being of such a length and number as may be deemed requisite. As soon as the process is completed, that dipped in cold water should be applied, and renewed from time to time during the lapse of two or three hours, when a poultice should be put over the injured surface. Cold seems to have a good effect at first in allaying the pain.

The chief advantages which I fancy the plan above described to possess is, that sudden excitement is produced over a large surface, whilst at the same time the whole skin is not destroyed and converted into a slough, as with the caustic or moxa, so as to leave a large open surface, which will heal but slowly, and will always leave a considerable scar. If, on the other hand, a round or flat piece of iron is applied even once to the surface, a slough must be produced, which separates more slowly, and leaves a more troublesome sore than the small lines of sloughs, and the consecutive sores, resulting from the practice above recommended.

Few agents in surgery have had ups and downs in fashion so repeated as actual cautery. From the days of William of Salicetus, and when discussions were held as to which method might be the best for the purpose, there have been varied opinions as to its efficacy. In my time I have noticed in my own practice and that of others that fashion or fancy has changed—I may refer to some four or six epochs in my own mind, and at present, so far as I can make out, the practice is in but little favour.

Among the different forms of counter-excitement, I may here allude to that which has been termed the pea-issue, and to the seton. The former is effected by means of placing a common pea, a glass-bead, a round bit of wood, or a pepper pellet, in a wound made on the surface for its reception, or on a sore already made with caustic, and keeping it there by means of a strip of plaster, so that it acts as a source of excitement and irritation,—the latter effect being further promoted by the addition of some stimulating ointment, such as the savine. So far as I know, this practice is but rarely followed in the present day; and I have myself, in the trials which I have made of it, seen no reason to induce me to recommend it in preference.
to others. The seton is a remedy which seems to me to be also in less repute than it once was. It is still, however, occasionally used, and from time to time individuals, somewhat advanced in years, may be met with, who are bigoted in its favour. Its supposed efficacy in averting apoplexy, and other affections within the head, still induces its occasional necessity, and the introduction of a seton is usually considered a surgical operation. The seton generally consists of a cord of worsted, cotton, hemp, or silk thread, passed through and under the skin for the distance of an inch or so. The back of the neck, or the arm, opposite the attachment of the deltoid, is usually selected for its locality; but it may be applied in any region of the body, as over the pubes, in the perineum, loins, or wherever else thought advisable. The thread is commonly conveyed under the skin by means of a large flat needle, about three or four inches long, and a quarter of an inch in breadth, such as is here represented (fig. 66) on a slightly diminished scale; but the necessity for this instrument may be avoided by using the bistoury and probe, which are instruments that cannot be dispensed with in the modern pocket-case. When the skin is lax, it

should be pinched up betwixt the thumb and fore-finger, and the blade of a bistoury should then be pushed through both layers; the point of the probe should then be carried along the flat surface of the blade, and the cord, which has been previously attached to its eye, should be drawn through after it. Inflammation in the track of the thread will be the speedy result, suppuration soon follows, and the excitement may be kept up for any desired length of time, so long as the foreign substance is allowed to remain, the savine ointment being occasionally useful in promoting further suppuration.

Objections have been made to threads of any kind being used as setons, owing to the filth which accumulates upon them; and I cannot but concur in this objection, although I have nothing to say in favour of the modern substitute in shape of a slip of tape covered with caoutchoue, which also, at best, is but a filthy affair, and often, by the irritation of its sharp margins, makes one glad to supplant it by the common thread.

As a counter-irritant, I place less reliance on the seton than other means already mentioned; but as a direct irritant it may be highly
esteemed: thus, in certain erectile tumours, in sinuses, in false joints, and in hydrocele, it seems to me of some value; but its application in these cases will be more appropriately considered in other parts of this volume.

Many other materials besides those above alluded to have been used as counter-irritants, such as sulphuric, nitric, and hydrochloric acids, corrosive sublimate, ammonia, arsenic, chloride of lime, quicklime by itself, or mixed with caustic potash, as in the Vienna caustic paste, &c.; but after having tried most or all of them, I cannot perceive any peculiar advantage belonging to any individually, and the accounts given of their mode of action by the different parties who advocate their special claims, are such as to show that their use must be attended with great pain and annoyance.

Caustics and cauteries have been used extensively by some surgeons as direct applications to diseased surfaces, and often with very striking advantages. Some patients will suffer any pain to avoid a cutting instrument, and there are certain parts of the body where, if the surgeon is unwilling to apply the knife, such means may be had recourse to with great propriety. Some time ago I had to treat a fungoid-looking tumour on the sole of the foot of a timid old lady; the wisdom of using the knife was questionable, and besides the patient was averse to such a mode of treatment. Here a strong caustic (potassa fusa) was used with the most happy result.

After frequent, and, as I trust, impartial trials, I am not yet convinced of the specific advantages derived from some of these caustics in the treatment of malignant diseases. I cannot perceive any difference in the actions of arsenic, chloride of zinc, acetic acid, &c., excepting that they are not so potent as many other substances; and it seems to me that there are none so powerful or so precise in effect as the actual cautery; I confess, however, that I do not admire its use in cases where it is intended to burn out diseases which are beyond the reach of the knife. In malignant tumours of the jaws, for example, the custom has been but too prevalent of cutting away the bulk of the disease, and trusting to the destructive powers of the cautery to eradicate the remaining portions. Wherever I have seen this done, no good has resulted; and although the beneficial effects of the plan in some instances may not be denied, I should be very unwilling to undertake an operation with such uncertain means of execution. In accordance with the precepts of others, I at one time applied it to carious surfaces; but have now abandoned it for the more efficient and more controllable means with the knife, forceps, saw, and gouge, to be particularly referred to in after parts of this work.
CHAPTER VI.
INFLAMMATION.

The practical surgery of this work will be found chiefly in those pages where the injuries and diseases of the different regions of the body are considered; but certain general principles are so universally applicable, as to induce me to refer to them at the present stage of progress; thus saving the necessity of frequent repetitions, and also being more in accordance with the nature of an introduction.

Inflammation is a disease which occupies a large share of the surgeon's attention, and fortunately for him the symptoms are generally so well marked as to leave little room for doubt as to the nature of the affection. The common local symptoms of pain, heat, redness, and swelling, are, in many instances, so very conspicuous, that no surgeon can for a moment be uncertain about the nature of the disease. There are many examples of this affection, however, wherein some of these local symptoms cannot be appreciated; but, the quick and full pulse, thirst, headache, dryness of the skin and mucous membranes, brown and dry tongue, buffy blood (if that fluid be drawn), high-coloured and scanty urine, will all give additional and certain indications of the disease. Some of these, even, are not entirely to be depended on, seeing that they may be present without the existence of inflammation; whilst, again, that disease may be in full vigour, and yet the symptoms may be such that the most experienced may be deceived. Exceptions to these observations must be familiar to every one who has seen even a little practice, and it must be acknowledged that ignorance or carelessness will occasionally produce most gross mistakes. One exception I think of sufficient importance to demand notice here—viz., the smallness of the pulse in inflammation of the peritoneum. It is a frequent subject of remark that the unwary are misled by this anomaly; but the experienced practitioner well knows that, after the reduction of a hernia, whether by the taxis or a cutting operation, it is generally a favourable symptom when the pulse becomes fuller, although it should beat somewhat quicker. If there be pain in a part, and if it depends on inflammation, it is not necessary that the surgeon should perceive either redness or swelling, to enable him to identify the disease; for, if the affection be deep-seated, these latter symptoms are seldom, if ever, to be observed, although the accomplished practitioner may not have a doubt that the disease is in full activity. Thus, in the chest these symptoms cannot be appreciated by the eye or touch; yet, by reference to the pulse and other symptoms, and an appeal to auscultation and percussion, the nature of the case, if it is one of inflammation, can scarcely be overlooked. Again, in inflammation of the cartilages of the hip or shoulder joints, neither redness nor swelling can be perceived; yet the pain which is experienced when the surfaces are rubbed against each other, is sufficient, with the other symptoms, to indicate the presence of the disease.
INFLAMMATION.

The treatment of inflammation and its consequences constitutes an extensive department of the practice of surgery, and as the disease is met with under so many different aspects and circumstances, even in the ordinary routine of the surgeon's duty, each probably requiring certain modifications, or perhaps decided alterations of practice, I shall now, in accordance with the plan of this work, proceed with such practical remarks on the kinds of inflammation likely to be met with in the diseases and injuries which it is my intention to discuss in the following pages, as may elucidate my own practice, and guide the young surgeon, until he has acquired sufficient experience to act on his own resources.

The common divisions of inflammation into acute, chronic, simple, and specific, answer sufficiently well for general purposes of illustration, although it is often difficult to determine the accuracy of these appellations. The terms "acute," and "chronic," in their ordinary acceptance, clearly indicate that in one case the phenomena of the disease are all developed rapidly, in another slowly; yet practitioners do not in all instances agree on the distinctions which may be thought to constitute acute or chronic action. For example, when inflammation attacks the female mamma, particularly during the period of lactation, if in the course of a few days a large quantity of pus is formed, and from the first attack up to the period of suppuration all the symptoms of inflammation have been well marked, the meaning of the term "acute" can scarcely be misunderstood; but, on the other hand, a swelling may form in the same part, progress slowly, and, after the lapse of months, within a couple of days, perhaps, there may be every evidence that matter has formed: here the term "chronic" is usually applied; but, nevertheless, the formation of pus has, in all probability, been a rapid—an "acute" process. The terms "simple" and "specific" are probably much more vague in their signification than those referred to: the latter implies a vast deal in the estimation of some, whilst with others there seems really so little precision in the term, that no importance is attached to it. Thus, no difference in action can be pointed out in inflammation and suppuration of an inguinal gland, occurring where there may be a venereal sore on the genital organs, or one arising from other causes, or where no sore—no apparent source of irritation is present; yet, in the instance of chancre many persons would consider the inflammation "specific." It may or it may not arise from the presence of venereal poison in the gland, yet the actions in either case seem precisely alike, nor will they be observed to differ from those occurring in an instance where the origin of the disease can or cannot be accounted for. Again, we consider certain appearances in the shape, size, colour, and condition of the frame, or its component parts, as indications of the state of constitution called scrofula, and the term "scrofulous inflammation" is in common use: yet, when this disease occurs in such constitutions, although the products of inflammation—even its effects on the system, may be peculiar, the actions constituting inflammation do not seem different from thos in ordinary constitutions. The term "specific," when applied in such cases, conveys to my mind no important signification, in so far as the inflammation
INFLAMMATION.

itself is concerned: but here I beg to be understood, that these observations apply chiefly to the kinds of inflammation which are met with in ordinary surgical practice.

The causes of inflammation are usually sufficiently clear to deserve the term "specific;" thus, a broken, or dislocated bone, is a distinct, sure, and specific cause of inflammation; so also is an eyelash, when it grows irregularly inwards upon the sclerotic or cornea; and the same may be said of stone in the urinary organs, or of a fish bone or some indigestible agent in the alimentary canal. The presence of a chemical, irritating, or corrosive material, of a foreign substance in any texture, such as a detached fragment of bone, a bullet, bit of wood, cloth, or other extraneous body, is almost certain to bring on the disease, and give it a more severe aspect, the latter resulting entirely from the "specific" irritation or cause. In such examples, the importance of distinguishing a cause must appear very evident; for if it be discovered, and within the reach or power of the surgeon, its removal, if practicable, whatever be the means resorted to for the purpose, forms the most important feature of the treatment. These means may be applied in various ways as the case may require, and if used with success, it seldom happens that nature does not complete the cure; for, under favourable circumstances (in a young and healthy subject, for example), no sooner is the cause of inflammation removed, than the phenomena of the disease gradually disappear, and the parts return to a state of health, as nearly resuming their normal condition as is compatible with circumstances.

The consequences of inflammation are often more conspicuous than the disease itself; as for example, suppuration, ulceration, granulation, and mortification, in all of which the symptoms of inflammation are thrown into the shade, as it were, by the remarkable features peculiar to each, and therefore the treatment of the disease, in all its phases, can only be rightly understood by one who is well acquainted with the nature of these different conditions. However, as it is, in general, a most desirable object to prevent any of these consequences occurring, the chief aim at the commencement of the treatment is to endeavour to do so, and to bring about what is usually called the resolution of the disease.—that is, to cause the subsidence of all the symptoms, and to leave the part as if no disease had ever been present. Although this is a result which cannot always be expected, it nevertheless often happens, and whenever it does, it is the most satisfactory that can possibly occur. If the means do not prove sufficient for this end, they may possibly mitigate some of the after consequences; they can seldom do harm; and, unless there be express indications to the contrary, they should, in some form or other, according to circumstances, be always administered. In one instance the disease, as it is evinced locally, will produce an effect on the constitution, so very slight, that the chief attention of the practitioner may be required and devoted to the seat of the affection, whilst in other examples the constitutional symptoms appear so overwhelming, that all his skill must be displayed in this direction.

It rarely happens that some kind of constitutional treatment will
not be of advantage, and in the early stages of the disease, the administration of purgatives, diluents, and diaphoretics, will seldom fail in producing benefit. These will often serve to bring the pulse to a natural standard; but the abstraction of blood by the lancet, from a vein in the arm, will frequently be required in other instances. It is impossible to state the amount which should be drawn in individual cases, for scarcely any two will be alike, either as regards the character, seat, and violence of the disease, or the constitution and condition of the patient: thus, in inflammation within the cranium, it will be much more correct to abstract a larger quantity than in the case of inflammation of the testicle; in an inflammation in the eye, it might be wiser to take blood more freely than in a similar disease in a lymphatic gland; and in inflammation of the lungs, it would be highly proper to bleed more copiously than in inflammation of the mamma. Again, a young and previously healthy constitution will generally bear the loss of blood better than one in which the energy of youth has become exhausted; and the inhabitants of a crowded city, from locality and other circumstances, are usually deemed less able to bear depletion than those of the rural districts. Different opinions are held on some of these points, however, even amongst the best authorities, and there are few of them which do not afford great scope for speculation. For my own part, when the lancet is deemed necessary, I am inclined to allow the stream to flow until some striking change is produced on the pulse, or other symptom, as the pain, or, in the lungs, the difficulty of breathing. When such changes are evinced, then the wound in the vein may be closed; in some instances the abstraction of ten or fifteen ounces will suffice; but in others thirty or fifty ounces may flow ere any benefit is derived. It often happens that the practitioner thinks it best to be contented with a certain quantity, perhaps ten or twenty ounces; but if the inflammation be severe or dangerous, and a decided effect is wished from blood-letting, then, as a rule of practice, I should say, that the above plan is preferable to that of judging of the effects of the venesection by the appearance of the blood. It may be hours before the surgeon can again see the patient—probably a day may have elapsed, and should it be found that in the cup occupied by the fluid last drawn, the buffy coat is most distinct, and should it happen, too, that the disease is not in any way ameliorated, then, if it is determined again to use the lancet, as in all likelihood it will be, there may be grounds for supposing that much valuable time has been lost. Perhaps, in many instances, the presence or absence of the buffy coat forms the principal criterion of the state of the disease, although it should not always be depended on; and in numerous examples, I believe the surgeon will do well to test the immediate efficacy of his practice by the apparent improvement of the symptoms, resulting from the method of blood-letting above recommended. The state of the pulse ought not always to be relied upon; for, as I have already mentioned, in some instances it may be smaller, and even slower, than in a state of health; and in certain conditions or peculiarities it may happen, that the heart’s action will be so far affected by less
INFLAMMATION.

of blood and other causes, as to give that feeling of fulness and strength which might lead to the supposition of a further depletion being necessary.

The above references to blood-letting were written many years ago, when venesection was among the commonest operations in surgery. Practice has so changed since, that they may seem useless, and quite behind the day in a book devoted chiefly to modern surgery. From old associations I cannot even now draw the pen through them; moreover, although as much a convert as most men to the modern practice of treating disease without directly abstracting blood, I entertain an idea that some change will yet take place, whereby the lancet may again come into use, although to a more limited extent than in former years.

Besides these measures, which may be said to constitute the most important part of the constitutional treatment of inflammation, there are others, often of the last consequence, such as mercury in certain cases of effusion, colchicum in rheumatic inflammation of joints, opiates to allay irritation, and stimulants to rouse the depressed and sinking powers of life. The exhibition of emaphor, ether, ammonia, and wine, may prove of the utmost value in certain cases, which form, as it were, the exceptions to the general practice of constitutional depletion, which is so universally admitted as being the proper course to pursue in the treatment of this disease. In some instances depletion may be carried too far, and unless the practitioner resorts to the use of stimulants, his patient's life will be placed in as great jeopardy by the over-zealous application of the means of cure, as by the original disease.

The diet of the patient may produce great influence for good or evil. It is seldom that authors or teachers neglect to caution against the use of animal food and exciting fluids in the early stages of inflammation, though, in fact, there is but little need to do so; for, so long as the disease is in full vigour, the patient loathes his usual diet, and when he does not, the affection can rarely be looked upon as of immediate serious importance. It seems to me almost unnecessary to inform the young practitioner that he should not insist on his patient partaking heartily of chop or steak, when he may perceive that he can scarcely admit a morsel into his mouth without experiencing nausea. If the disease has really been formidable, it may be deemed a most favourable symptom when the patient asks for food; and at this period there may be a necessity for caution, as over-exciting food, either from quality or quantity, may induce a return of the disease or greatly retard the progress of cure. It may be requisite, in certain examples, to keep the patient on low diet, not so much for the purpose of curing inflammation, as with a view to prevent its commencement or extension. For example, if a person suffered concussion of the brain from a blow on the head, it would be highly improper to permit full diet, as in such a case, after the first stunning effects have gone off, there may be good reason to dread the occurrence of inflammation; again, if an important joint be wounded, or a large bone severely fractured, a generous stimulating diet might produce those very results which
INFLAMMATION.

is the object of the surgeon to obviate, viz., an excess of inflammatory action.

In certain kinds of inflammation, and in certain stages, a full amount of nourishment, both in the way of food and drink, may be productive of the utmost service; and where digestion and assimilation seem to go on favourably, and whilst the disease seems to improve, it will rarely happen that the practitioner is wrong in permitting their use. In severe local inflammation, such as that of carbuncle, occurring in a debilitated constitution, accustomed perhaps for years to the artificial stimulus of ardent spirits, the latter should not be omitted; and if the stomach will bear the additional excitement of a generous and wholesome diet, the system will hold up more vigorously against the depressing effects of disease. Again, in cases of profuse discharge happening at any period of life, nourishing food and a fair proportion of stimulating fluids will be of advantage, provided always that the indulgence does not seem in any way to aggravate the ailments of the patient. At such a period possibly hectic fever may exist, and might be aggravated by an over-liberal allowance. It is, however, impossible to offer set rules as applicable to all kinds of cases; much, therefore, must be left to the good sense of the practitioner and discretion of the attendants, or of the patient himself. Among the educated classes, the surgeon has seldom any difficulty in having his wishes and orders fulfilled to the letter; but in the lower ranks it is often necessary to be exceedingly strict and cautious.

The local treatment of inflammation constitutes the peculiar feature of practice, in a large proportion of cases of this disease which come under the surgeon's care. In many instances the administration of a purge, and some slight modification of diet, such as an intelligent patient might himself adopt, may form all the constitutional treatment required. Local abstraction of blood seems almost always to have a more decided effect on the disease than when a large vein is opened at a distant part; thus in inflammation of the testicle, of a joint, a bursa, or, in short, any similar local forms of the affection, and whether depending upon a local or constitutional cause, this mode of depletion is, in my opinion, more to be depended upon than the other, although here also there are many exceptions to a general rule. Sometimes, indeed most frequently, it is impossible to reach the actual seat of the disease, as in inflammation within the cranium, the eyes, the ears, spine, hip-joint, and other articulations; yet in such examples if blood be drawn from the temporal artery or external jugular vein, from over the mastoid process, the spine, or fleshy mass of the hip, more benefit will, in general, result from operations on these parts than by opening a vein at the arm. In violent forms of the disease, both may be combined. In erysipelas, or in severely inflamed wounds or ulcers of the skin, or of certain parts of the mucous membranes, local depletion, in the strictest sense of the term, can be readily applied, and in such instances the effects are usually very beneficial.

Blood may be abstracted locally, by such means as have already been referred to (pp. 55, 56); and if the part actually affected with
inflammation is near or on the surface, I should, in general, prefer leeches, as the method by scarifications, either with or without the cupping-glasses, is usually attended with more pain, and may possibly leave greater marks than those resulting from the leech-bites.

Whatever be the means employed for local depletion, warmth is always of service in promoting the flow of blood: whether local bleeding has been resorted to or not, it is seldom that it does not produce a soothing effect on the patient's feelings:—indeed, I believe that it has a specific advantage besides, in encouraging a more general diffusion of blood through all the vessels of the affected part, and also in those immediately around,—at the same time causing the exudation of serum on the surface, and thus, as it were, lessening the quantity of fluid in the seat of disease. Whether these explanations be correct or not, I have no hesitation in recommending warmth as an excellent mode of treating inflammation locally. It should be applied by means of fomentations, or by steam, as was recommended in preference by Dr. Macartney, by dipping the parts into warm water, by keeping moist cloths over them, or by a poultice. Fomentations are usually applied with a sponge or bit of soft rag. Cloths (surgeons' lint, linen rag, or soft flannel) are usually wrung out of hot water, and their efficacy is greatly enhanced by covering all over with oiled silk, a film of gutta percha, or Mackintosh cloth, which have the double effect of preventing evaporation (thus preserving the warmth), and keeping the bed-clothes dry. In many instances Markwick's spongio-piline is of admirable use. These means are often greatly to be preferred to the poultice, although the latter cannot always be dispensed with. In slight inflammation of a finger, for example, if warmth were required, instead of using a poultice, the part may be wrapped in wet lint, and covered with oiled silk. Moisture and heat are thus more effectually secured than by a poultice, which will soon get cold on the surface, and in a few hours become almost dry. On other parts of the body this plan, modified by circumstances, may be resorted to with every advantage, and I cannot speak in terms too laudatory of the "water-dressing," as this method is now usually called, which under the recommendation of Percy, Larrey, Kern, Macartney, Liston, and of many practical surgeons of the day, has in a great measure superseded the more troublesome and more cumbersome poultice.

It is often customary to use decoctions of chamomile flowers, poppy-heads, solutions of acetate of lead, of opium, or other sedatives, as fomentations. Such adjuncts seem occasionally to allay pain and irritation, but in the majority of cases, I believe that warmth and moisture constitute the chief virtues of fomentations. The same fluids have been used to moisten the materials of which poultices have been made, the latter being usually formed of bread, bran, linseed powder, boiled carrot or turnip; and sometimes they seem to enhance the value of the poultice.

Besides the efficacy of warmth as an immediate application to an inflamed part, I believe that when used on the surface, even in deep-seated inflammation, it is of service in encouraging the flow of blood.
to the superficial parts;—thus relieving the deep-seated vessels, and acting much in the manner of a counter-irritant. In the latter light, too, I look upon the supposed efficacy of bags of heated bran, salt, or sand, which are favourite remedies with some practitioners.

The immediate application of cold has, in most instances, a most decided effect on inflammation; but if it does not come into close contact (which is the sense in which the term "immediate" is here used) with the disease, and the greater part of it too, I am doubtful if it produces the benefit which some seem to imagine. It has a good effect in allaying the heat and pain of a slight burn or scald;—perhaps in such cases, if applied at an early date, it prevents inflammation; but in the severe form of such injuries its use is inadmissible, or at all events very questionable. In certain cases, as, for instance, an inflamed testicle, it seems to diminish the quantity of blood circulating in the superficial vessels, but it probably throws more into the deeper ones, and thus increases the patient’s suffering. That such is not always the result here, as also in other parts, may be admitted, for, were the above argument invariably correct, the utility of cold, in injuries of the head, might be doubted; and though, upon the whole, warmth may be preferred to cold, as a local means of treating inflammation, I would, in many instances, trust greatly to the feelings of the patient, and the seeming effect of the remedy otherwise, in persisting in the one or the other.

Cold is seldom used where local bleeding has been resorted to. It is generally applied by means of water, with ice, if convenient, or by some saline combinations in solution. Occasionally the affected part is placed in cold water, and the plan of keeping a surface constantly moistened by means of a broad tape (a common roller, for example), which has one end in a basin of fluid placed above the level of the patient, and the other on the seat of disease, so that the water shall flow as through a syphon, serves most excellently. Dr. Macartney recommended such a method in preference to that of "irrigation" used by the French, whereby the water was permitted to drop upon the part from an apparatus placed above.

Counter-irritation is a remedy of great power, I believe, in certain cases and forms of inflammation, as already pointed out in a previous chapter, but it is often, in my opinion, much abused. In the early stages of deep-seated inflammation in the spine or hip-joint, the excitement of a new action or disease on the skin, at some distance from the structures seriously affected, generally produces benefit, but after caries has been established it may be doubted if it is of the smallest advantage. On this subject, however, I shall be more explicit afterwards, in my remarks upon caries.

Counter-irritation is effected in various ways, already particularly referred to in the fifth chapter. The method of applying it, in most general use, is by the common blistering plaster of cantharides, or the sinapism of mustard; and when a severe and more lasting effect is wished to be produced, the potential or actual cauteries may be resorted to, or the seton, according to the nature of the
case, or the supposed efficacy, or applicability, of one or other of these measures.

Most of the direct applications to inflamed parts may be said to have a soothing and sedative effect on the disease, and I believe that nothing tends more to a happy result of treatment, than complete repose both of body and mind, combined with a favourable adjustment of the affected parts. For example, if in inflammation of the leg, resulting from such slight cause as the pulling out of a hair, the patient persists in standing or walking much, and moreover takes no care to prevent the surface being fricected, the disease usually assumes a much more troublesome character than would otherwise have been the case. Here, rest, and the horizontal position of the limb, might have saved much trouble. There will be so many opportunities afterwards of pointing out the advantages of quietude and of favourable position, in local inflammations, that I need not dwell on these topics at present;—indeed, I have referred to them in this place, chiefly for the purpose of stating, that sometimes the reverse of soothing and sedative measures is recommended to inflamed surfaces: thus, blisters, tincture of iodine, and lunar caustic have been used in erysipelas; but my own experience would induce me to eschew such means, although in certain chronic forms of inflammation, as of the conjunctiva, or in callous ulcers of the legs, direct stimulants are certainly of service; the application of sulphate of copper, nitrate of silver, vinum opii, and other such irritants, being useful on the eye, whilst on the legs, even blisters have been applied with great advantage.

CHAPTER VII.

EFFUSION OF SERUM AND OF LYMPH.

The general treatment of inflammation may be further illustrated by reference to some of the consequences of this disease, and partly on this account, as also to carry out the objects of this introduction, I shall now proceed with the consideration of such of them as shall serve the purposes in view.

Pain, heat, and redness, may all be subdued by those local and constitutional measures of treatment which have been adverted to in the preceding chapter; even swelling may be prevented, or may subside under the use of cold. Perhaps, however, this symptom of inflammation, after it has once become conspicuous, disappears more slowly than any other. It is certainly, in general, aggravated by warmth and leeches,—by the latter in particular, but unless it increases amazingly, it is not much to be regretted; on the contrary, I believe that diffusion of swelling is a beneficial occurrence, for in instances of inflammation in textures and parts of the body where this cannot happen to any very perceptible extent, other symptoms of the disease are invariably most distressing, as is exemplified in inflammations of the
EFFUSION OF SERUM AND OF LYMPH.

periosteum, bone, eyeball, ear, and under aponeuroses. But in certain instances, and these, too, not of rare occurrence, swelling becomes so remarkable, or is so peculiar in its character, as to require some appropriate treatment, different from that resorted to in ordinary inflammation.

If swelling is dependent merely on enlargement of blood-vessels, it can never require much treatment solely as swelling, although the relief of the over-distended vessels, by the measures already referred to, viz., drawing blood from their immediate vicinity, or by their actual division, may be of great service in checking the disease; but if this condition depends on any of those forms of effusion which so frequently follow as consequences of inflammation, then the aid of the surgeon may prove of great value.

In some parts of the body swelling constitutes one of the most conspicuous symptoms of inflammation,—as in the eyelids, serotum, or prepuce. In these situations it is almost invariably the result of effusion of serum into the cellular texture, which, once the active form of disease has ceased, disappears almost as rapidly as it may have come. In other parts of the body similar swelling may exist, the term oedema being that in general use to designate this condition. When a part is in this state, it is always easily recognized from any other kind of swelling, from the dimple which is left after the foreible application of the finger, and probably by the shining and partly transparent appearance of the skin. A similar condition may be present independent of any apparent inflammatory action, as in the swollen state of the body which occasionally follows scarlet fever, or in anasarca resulting from diseased heart or kidneys. From whatever cause it may arise, the surgeon should remember, that unless the part affected (supposing the condition to be entirely local) be supported on a level with the rest of the body, or, at all events, be kept from a very dependent position, the swelling is almost certain to increase: hence the excellent rule of elevating a part affected with inflammation or any action of a somewhat similar kind. Thus in the serotum, if this species of enlargement is not attended to, and supposing the patient to be confined to bed, the swelling gets between the thighs, or falls so low between the groins, and produces so great distension of the skin, that ulceration, or mortification, may actually occur: again, if in like condition of the hand or foot, these parts be allowed to lie below the level of the rest of the body, the same results may happen. By suspending the serotum properly, or keeping the other parts sufficiently high, all such dangers may be avoided; and, indeed, unless position be properly attended to in the treatment of accident or disease, the state of oedema is exceedingly apt to occur,—even a little irregular pressure, from a bandage, or other cause, may occasion the same result. As a proof of the advantage of position in such cases, I may refer to the condition of the face, and particularly the eyelids, in ordinary anasarca: during the night, when the patient is in the horizontal position, those become much swollen: but during the day, when he sits up, or has the head elevated, they assume their natural appearance, owing to the
serum gravitating towards the more dependent parts. Here there is little to be done, unless by constitutional means which shall act upon the absorbents and kidneys, but which need not be particularly referred to; indeed, I allude to the circumstance for the sole purpose of showing the advantage of elevating a part, which happens to be in an oedematous condition, above the rest of the body, in as far as that can properly be accomplished. Sometimes the swelling of oedema seems so much greater than the skin can bear with impunity, that it is advantageous to make punctures with a lancet to permit the escape of serum. This practice has, with some surgeons, the additional recommendation of permitting at the same time the flow of blood, and thus alleviating inflammatory action. In erysipelas, for example, more particularly in the head and face, where the disease is often attended with great swelling, the plan of puncturing with a lancet has been much followed. I have often myself resorted to such treatment, especially in the oedema which attends the severe forms of phymosis and paraphymosis; but position, and the exhibition of a smart saline cathartic, may do much to obviate the necessity of the lancet. In acute forms of this kind of swelling, the last-named means of treatment, and those usually followed for inflammation, may put all to rights again; and in certain cases, where the action seems chronic, friction, or the application of a bandage, may be of service; both, however, must be used with caution, and any irregularity of pressure, by the latter means, must be avoided, for whatever impedes the venous circulation seems to conduce greatly to effusion of serum, as may be frequently seen in fracture of the upper end of the humerus, in which case, unless, while adjusting the splints, pads, and bandages, the hand and fore-arm are enveloped in a bandage also, and in addition suspended in a sling, there is every probability of oedema coming on.

In certain forms of inflammation, instead of serous effusion there may be an exudation of lymph, and when this occurs in textures it may also occasion swelling, which is usually designated solid oedema, in consequence of the accompanying hardness, and in contradistinction to that resulting from the presence of serum. It generally seems to be the effect of more chronic action than that which induces infiltration of serum; yet this is by no means always the case, for sometimes serous effusion seems to be brought about by a slow irritation, whilst, on the other hand, lymph may be poured out within a few hours after the application of an exciting cause. As an illustration of the latter statement, I may refer to the rapid exudation of lymph succeeding to wounds, occurring, as it does, within a few hours after such injuries. Swelling resulting from the effusion of lymph seldom acquires any magnitude, and is rarely such as to demand active surgical interference. In those cases where it is most common, such as in erysipelas, wounds, stumps, fractures, and dislocations, time alone may be trusted to for its disappearance, as absorption is sure to occur, provided all source of irritation be removed. In some of these cases, however, the diminution of the swelling may be expedited by stimulants, such as friction with the hand or flesh-brush, or stimulating liniments, douches, and
SUPPURATION.

pressure by bandages. In some instances, too, where the swelling and induration seem peculiar to, or dependent upon, a specific condition of the constitution, as in certain kinds of chancre, or in a soft node, the internal or external exhibition of mercury or iodine, singly or combined, has a most beneficial effect apparently, although occasionally it may be doubted whether, when swellings disappear under the use of these means, the benefit is to be attributed more to their efficacy, than to the time occupied in their application.

Sometimes the lymph effused as the result of inflammation, forms a swelling so permanent, and, at the same time, so troublesome to the patient, that there may be every justification in using the knife for its immediate and effectual removal. The necessity for such a proceeding is by no means unusual on the prepuce, where solid aëdema is an almost certain result of long-continued inflammation.

CHAPTER VIII.

SUPPURATION.

The presence of pus is a result of inflammation, which often adds greatly to the swelling, and is one of those consequences of this disease which affords apt illustrations of the treatment of certain conditions resulting from it. This fluid may, like serum, be effused on any surface or in any texture of the body; but, for present purposes, it will be best to refer to its formation, only in those where its presence is most interesting to the surgeon.

Although, in general, this consequence of inflammation is a most unfortunate one,—as, for example, in erysipelas, in inflamed glands or joints, or in many other kinds of the disease in different parts of the body,—it is nevertheless earnestly to be desired in some instances. In effusions of serum, or of lymph, where there is little or no breach of continuity, or of surface, absorption may remove all traces of these conditions, and that consequence or termination of inflammation called resolution may ensue; but when pus has been secreted it rarely happens that it is absorbed; it must be discharged from the body by a breach of the surface, and, unlike the favourable cases of resolution, there must always be some mark left, to denote ever after, that disease and injury have been present. The case, also, will usually be more tedious, and there is greater danger to limb or life when suppuration occurs. Hence, then, the anxiety of the surgeon to arrest the progress of an inflammation ere suppuration commences.

The occurrence of suppuration often produces alleviation of all the most distressing symptoms of inflammation, both local and constitutional; and, although this may be doubted in some cases, there are certain forms of injury and disease where such a result is most apparent, and when, in consequence, the practitioner from the very first encourages the event. Thus, in lacerated wounds, when there is no
possibility of union by the first intention, and in wounds where irritating materials have been left behind, suppuration is not only productive of the benefits above alluded to, but is also a stage in advance towards a cure. It is almost universally admitted that the formation of pus progresses most favourably under warmth, and hence, then, in such cases, the surgeon assiduously applies it by one or other of those means already adverted to. Here it may seem strange, that the same means are adopted to encourage suppuration that are considered most efficacious in arresting inflammation; yet, according to the explanations already given of the supposed efficacy of warmth in this disease, and what I have lately stated of the beneficial results of the process, this remedial agent (warmth) may be considered to act favourably in inflammation, whether in one case it arrests its progress, or in another it hastens on the suppurative stage, and thus in a great measure changes the aspect of the disease. Why it should produce these different effects cannot readily be explained, nor can the most experienced surgeon always be certain which result will ensue.

It is often a point of much interest to determine whether suppuration has actually occurred or not. When it happens on a surface, the physical characters of the secretion are usually sufficiently clear to denote the circumstance: but if it takes place in deep-seated parts, there may not be the same facility for discrimination; so, whilst in some instances the event can scarcely be doubted, in others the most experienced practitioner may be at fault. The only characteristic constitutional symptom denoting the first formation of matter, which has been deemed of much consequence, is that of shivering; but it is, in my opinion, less worthy of estimation than some seem to imagine:—it frequently happens in instances of disease where suppuration never ensues; it often occurs, even in a state of health; and equally often when it does happen, it may be overlooked. Shivering is a symptom which the surgeon is often deeply interested in, not so much, however, from the dread of suppuration, as that it denotes some peculiar condition of the system fraught with much danger of life,—as for example, if within the first ten days after a capital amputation, or after lithotomy, a patient is seized with shivering, there is much reason to anticipate a fatal result; and although this may not occur in all such instances, every practical surgeon must bear me out in the formidable estimation I have made of this symptom. But whether it has preceded suppuration or not, the surgeon will seldom be thus satisfied that matter has formed. Swelling is not always a good criterion either, for though in some cases the continued accumulation of matter produces most perceptible enlargement, tumorfaction sometimes actually diminishes as matter is formed; whilst, in other instances of inflammation, it is conspicuously present, although suppuration is known to be a rare result, as in the eyelids, scrotum, and testicle. The undulatory motion of the fluid, produced by percussion with the fingers, is one of the surest symptoms of suppuration having occurred: the feeling of fluctuation is well understood by the person who has once placed the fingers of one hand over the collection of matter, and
SUPPURATION.

79
tapped gently on the swelling with those of the other. But some surgeons seem more acute in their perceptions than others; and it is with all more difficult to detect the presence of matter when it is deep-seated and in small quantity, than when superficial and in abundance. Some practitioners trust chiefly to the sense of touch, and the history of the case; occasionally the eye alone suffices; whilst in other instances where there is doubt, some exploring process may be resorted to, such as those which are described at p. 12.

It certainly seems awkward when a surgeon applies a cutting instrument, in hopes of reaching matter, that none appears: besides the unnecessary pain and injury inflicted on the patient, there is a display of want of tact on his part. Some, therefore, will not interfere until the presence of pus is so palpable that a mistake cannot possibly occur. There are surgeons who avoid exploration of any kind with instruments, because they fancy that this implies an individual want of skill. It happens frequently, however, that practitioners of great experience are uncertain, and as it may be of great consequence to decide upon the nature of a swelling, so that the proper course of treatment should be arranged, I consider the use of the exploring needle a legitimate means of acquiring knowledge. A small trocar and canula, such as that afterwards displayed on the page referring to puncture of the head in hydrocephalus, may be used for exploring, but a grooved needle, such as that here represented (fig. 67), makes

*Fig. 67.*

the best instrument. When the point is pushed into the swelling, if fluid be present, it will rise through the groove, and thus the question will be settled.

Suppuration occasionally occurs without any well-marked inflammation, as is exemplified in those collections of matter known under the appellation of "cold abscesses," and in these cases the sense of touch will be the chief guide for the surgeon. In the generality of instances the preceding inflammation will rouse suspicion, especially if the pain has been of an intense and throbbing character, for the latter symptom may almost be deemed coincident with the suppurrative action. If there is much swelling from oedema, as there usually will be in severe inflammation (for oedema commonly indicates the violence of the disease), the fluctuation may not be very perceptible, as the parts will not be so elastic as a common bag of fluid; yet if the seat of disease be supposed or ascertained to be deep, the infiltrated condition of the parts on the surface, and therefore at a distance, will, if allied with other indications, add force to the supposition that matter is present. Occasionally the surgeon will be puzzled in examples of swelling and inflammation resulting from blows. Perhaps in an example of the kind, the tumefaction will at first be, to the touch, of the same consistency throughout; but in the course of six or eight
days it may rather suddenly become soft in the centre, fluctuation being quite distinct. Here, possibly, the fluid may be blood, which has gradually accumulated in a semi-fluid state in the particular spot. The presence or absence of indications of inflammation around, will probably decide an opinion in such a case; for if the symptoms of that disease be not very conspicuous, the chances are that the fluid is blood, and not matter. These observations are well illustrated in contused wounds of the scalp.

CHAPTER IX.

ABSCESS.

When there is full assurance that matter is actually present, the plan of treatment may yet be doubtful. The surgeon may have to determine whether he will trust to nature to produce absorption; whether he will resort to such means as are thought conducive to this end; whether he will allow the matter to be discharged spontaneously, or give it an exit himself; and, in the event of resolving on the latter course, what period and what means will be the best for that purpose. There cannot be a doubt that large abscesses have occasionally been absorbed, and everyday experience shows that small collections of pus will disappear, either spontaneously or under the supposed influence of remedies. It would be improper in most cases, however, to entertain sanguine hopes of such an event occurring; but, in general, little harm can result from any attempt that may be made to excite the action of the absorbents. Some of those means which have been referred to in treating of absorption of lymph, may be tried here; perhaps the external use of iodine, of mercurial ointments, singly or combined, may be of much service, whilst sometimes a blister may have the desired effect. It may as often happen, however, that these either produce no perceptible benefit, or that they actually conduce to the suppurative action. The blister is most apt to have this latter effect; indeed, so great is my conviction on this point, that I order a blister, as frequently with the view of inducing a rapid and probably an increased accumulation of pus, as from any hope of absorption being excited. When absorption has occurred in my own practice, it has generally been under the use of poultices, which had been applied for the purpose of promoting suppuration, or else of bringing the matter towards the surface; and I have in such instances attributed the disappearance of matter more to time and natural results than to any peculiar action of the poultice, which, as already stated, is considered one of the most certain means of producing suppuration.

In all cases of suppuration, wherever the matter is first formed or deposited it shows a remarkable tendency to approach the outer surface of the body. In some instances it will pass towards some neighbouring surface or cavity; but in whatever direction it proceeds, the
tissues gradually fade, the wall of the abscess becomes thinner, and ultimately an opening may form through which the matter will flow seemingly of its own accord, an action induced doubtless by the elasticity and pressure of the surrounding parts. The progress of an abscess towards the surface may be slow or quick, in accordance with peculiarities in the case or the mode of treatment, but it is as sure as any other action natural to the system. In such cases the tissues are said to be absorbed. Possibly, whilst absorption is thus going forward, some matter is taken up also, and the same doubtless happens with the lymph, which lies around the abscess, and gives thickness and solidity to that part which is called the cyst, in which matter lies. Some have doubted if matter ever is absorbed, but it seems to me as easy to understand this action upon the matter as upon the lymph, or the tissues which gradually give way as the abscess progresses towards the surface.

It is, I imagine, too much the custom to allow matter to be discharged naturally. In most parts of the body, if the suppuration be deep-seated, the pus may extend widely, and do much harm by the separation of textures, ere it can reach the surface; and even when it does so, and is discharged through some small opening, it rarely happens that the interior of the abscess closes entirely;—a discharge continues long afterwards, and ultimately the interference of the surgeon is required. From this it may be seen that I am averse to leaving such cases entirely to nature; occasionally the surgeon cannot do otherwise, and sometimes, even with all his care, matter will burst forth when he does not expect it. If an abscess in the perineum, for example, be left for a day or two, under the supposition that the delay will be advantageous, even though it may be intended to use the knife to open it, the practitioner is often amazed to find that the matter has, in the lapse of four-and-twenty hours, made an exit through the skin or mucous membrane in the vicinity of the anus,—yet it seldom happens in such instances, that the knife is not ultimately required.

The period for giving exit to matter will vary according to circumstances. Thus, if it be extensively diffused, as in phlegmonous erysipelas, where it may separate the skin from the textures underneath to a most injurious degree, the sooner a free vent to the matter is given, so much the better; and here, too, if the knife be used, there seems an additional advantage, as has been pointed out by Sir William Lawrence, in the loss of blood occasioned by the division of engorged vessels: again, if the pressure of matter seems to produce great pain, or if its continued presence is likely in any way to occasion additional harm, such as by bursting into a cavity, laying bare a portion of bone, or of a large vessel; or if from being under an aponeurosis, there is greater chance of its being diffused beneath that membrane than making its way to the surface, then it should be permitted to escape through an incision made at an early period. However, excepting under these or other equally pressing circumstances, I must declare myself an advocate for delay in opening abscesses. Besides the hope,
though it may be but slender, of absorption occurring, I am of opinion that in ordinary abscess, a bubo, for instance, if an opening is not made until the matter has approached near to the surface, the subsequent progress of the case is much more rapid and satisfactory, provided that a proper opening be made. I have seen a good deal of the practice of making early openings, and have invariably observed that more pain was thereby induced, and seemingly, too, an additional amount of suppuration, whilst the after-treatment has been remarkably tedious. My opinion has already been stated in a preceding page, that in some instances the occurrence of suppuration actually produces an amelioration of many of the distressing accompaniments of inflammation; but if, before the process has gone almost to its full extent, any incision be made into the affected parts, the injury thereby inflicted upon them, will, to say the least of it, be a most un

timely interference. That in all instances of supplicative inflammation this is not the case, may be readily admitted; and the examples cited above, to inculcate the necessity for an early opening, will show that I entertain many exceptions: but in the case of bubo in the groin, or other such abscess, I am decidedly inclined to delay, until the parts over the matter become much thinner than they may have been at first, or, in other words, until the fluid has come nearer to the surface, and perhaps actually threatens to burst forth.

When an opening is required in cases of suppuration, I give a preference to cutting instruments for the purpose. Excepting in rare and peculiar instances, I deem the caustic potash a cruel and unwarrantable application. In a small collection of matter, the point of a needle or pin may make a sufficient opening, or that of a lancet may at all events suffice; but when the abscess is large, in my opinion a scalpel or bistoury should always be used. In the case of a bubo, containing perhaps an ounce or so of matter, the wound should be about an inch long, so as to expose fully the interior of the abscess. In general, the thinnest part of the skin should be selected, where the matter is said, in technical language, to point, and the incision should be made in the longest axis of the swelling, though sometimes the latter rule may be deviated from, for the sake of having one end of the opening in such a position as to give free passage to matter afterwards, or possibly for the purpose of cutting parallel with some particular part, or in other instances across such textures as might seem to require division.

If a lancet is used in any of these operations, it may be held in the manner referred to at p. 55; and if the bistoury is selected, the attitude exhibited at p. 53 may be chosen, but it is by no means a safe one for such purposes; by a sudden plunge, or by a movement of the patient, it may pass too deep; and I therefore prefer that represented in fig. 68, in which the little finger, resting on the neighbouring surface, is a safeguard against such an occurrence. The point of the instrument should be thrust into the matter, and the blade should then be carried to the desired extent through the textures, by a movement with the extremities of the thumb and two first fingers. The edge of
the knife may be carried in any direction, and consequently some slight deviation from the position here shown, must be requisite.

Such an attitude as that in fig. 69, I think good; the forefinger of the left hand, and perhaps the middle also, being placed over the abscess with a gentle pressure, the back of the knife should be caused to rest against the side of the forefinger, as here represented; the point should then be thrust through the skin and the coverings of the matter divided as far as may be thought sufficient. This attitude I deem best suited to cases where pus is deep-seated, and when, probably, the surgeon has misgivings as to its presence at all. When the point of the bistoury is supposed to have reached this fluid, the blade may be gently turned a little on its long axis, and, probably, the pus will spring up, along its surface; or a director as referred to at p. 14, may be pushed through the wound alongside of the blade, which, having thus served as a guide, may be withdrawn, or used to enlarge the opening as may be thought best.

For many years I have been in the habit of using instruments of this (fig. 70) shape, for opening abscesses. In former days it was recommended by the late Dr. Saunders of Edinburgh; and when I was young, was, if I am not mistaken, used by Mr. Syme. It passes now, among my own pupils, as Syme's abscess lancet. The fine point, double cutting edge, and slight curve, all seem to me well fitted for the object in view, and in general I give a preference to this instrument over all others, for opening abscesses. It may be held in the hand like the ordinary bistoury, as represented in fig. 4, or it may be held as in fig. 68; or it may be used as in fig. 71, which will probably be the most convenient way of any. The little
finger resting on the surface will prevent any hazardous plunge, while sufficient force can be applied to carry the point of the instrument through the skin. In many instances wherein opening an abscess is

Fig. 70.

required, it is of great consequence so to use the left hand as to cause projection of the fluid, at the point where the cutting instrument is to be introduced.

In opening the abscess, whatever be the instrument used, I invariably prefer puncturing first, and then enlarging the opening, to the method

Fig. 71.

pursued by some, of making a sort of dissection, by successive incisions through the skin and other textures. The puncture is usually made in the most prominent part of the abscess, and as this is generally the middle of the sac, it will be requisite, when the free incision is deemed expedient, to carry the knife in both directions from the original puncture. Indeed, in some cases a triangular or crucial incision may be required, or possibly the surgeon may think it advisable to divide the tissues in almost every direction, as he does in certain cases of complicated sinus or fistula.

When an abscess is freely opened, as above recommended, the whole surface is exposed to the air, and to the contact of such dressings as may be deemed advisable. Within a few days the whole cavity, supposing all things to go on favourably, is covered with red granulations; and these, with the contraction of the sac subsequent to the evacuation, serve to diminish the space, until ultimately, as cicatrization is completed, it is nearly, if not entirely, on a level with the contiguous skin. After the opening is effected, slight pressure with the fingers
may be made to squeeze out most of the matter; a long narrow strip of lint should then be introduced through the orifice, and allowed to remain for a couple of days, until suppuration is established on the cut surfaces; in the interval a poultice, or the water dressing, as recommended at p. 72, should be applied and continued until the granulations fill up the whole space to a level with the surrounding surface; then simple ointment, thinly spread on lint, should be made use of, and from time to time the sore should be bathed with a solution of sulphate of zinc or of copper (gr. ij ad $\frac{1}{2}$j), until it is healed over. Some little variety may be required occasionally, as will be more fully explained in my observations on the treatment of granulations.

I have said above that slight pressure with the finger or hand may be made, but I may here warn the young practitioner against doing more. Usually the lining of an abscess is so soft, and, possibly, so vascular, that very little pressure will cause rupture of minute blood-vessels; the blood from which, if it does not flow away at the time, or come in clots afterwards, may naturally alter the character of the discharge, and will, at all events, show that more violence has been applied than the circumstances admitted. The escape of a small quantity of blood can scarcely be avoided in such cases, but it seems the result of wanton rudeness when much is thus caused to mingle with the matter which it is alone the surgeon's object to get away.

Although I strongly recommend a free opening with a cutting instrument, in the treatment of ordinary abscesses, there are certain instances when such practice is objectionable, or, at the least, of questionable utility. In large collections of matter the system may not bear up against the extensive inflammation and its consequences which must follow the exposure of so large a surface; and it is good practice in such cases to ascertain in how far the cyst or sac of the abscess may be made to diminish by gradually lessening the quantity of fluid. This is the object in view in resorting to such means as are supposed to produce absorption; but as these are so seldom of service, it may be done by evacuating the contents gradually, and at different periods, through small punctures with the lancet or bistoury, after the manner recommended by Abernethy. If, for example, a lumbar abscess, pointing in the groin or loins, is opened by means of a small oblique puncture, a considerable quantity of the fluid may escape,—as much, perhaps, as the natural elasticity of the parts will cause to flow out,—and then the little wound being closed so as to heal by the first intention, the patient may, after the lapse of twenty-four hours, when the aperture is permanently healed, be in no respect injuriously affected by the proceeding, but there will be probably six or twelve ounces less fluid in the abscess. If similar proceedings are repeated again and again, each one in succession being done before the disease has attained the size it was on the occasion immediately preceding, then, at last, the cavity will have diminished so much, that its whole interior may be freely exposed at once, as in the treatment of abscesses of a smaller kind. This practice is well worthy of commendation; but, like many other really good measures, it does not always succeed; the puncture may not heal, and
there will be a continued drain of fluid through it; inflammation may extend from the wound into the sac; the nature of the secretion will then become much altered; possibly a few globules of air, entering through the aperture, may cause putrefaction or other important change; and supposing even that none of these evils have occurred, and that the sac has diminished as desired, a sinus may still remain which will baffle the best skill. However, even in this condition, it must be admitted that the patient is in a better state than with a large abscess. Sometimes bad results will follow the first operation; but in general everything goes on well until the third or fourth, when possibly there may be an excess of inflammation, and the puncture does not close: by this time, however, there is less danger than previously. I have frequently tried this plan, and, from experience, can speak highly in its favour. I treated in this way, in King's College Hospital, a very large abscess, situated chiefly in the iliac fossa and upper part of the thigh (see *Lancet*, Nov. 6, 1841): by repeated openings in the latter region, the matter was entirely evacuated, whilst the sac gradually contracted and ultimately closed. In this instance, the lower part of the abscess opened again after the lapse of several months; but the whole of the large cavity which must at one time have existed in the iliac fossa, remained permanently obliterated. I refer to this case chiefly on account of the latter circumstance, as it is by no means unusual for a part of an abscess to open up again, after being supposed to have closed entirely; and these sinuses, as they may be termed, are often more troublesome to deal with than the original disease.

Sometimes in the treatment of suppuration, several openings should be made at the same time, to permit a very free discharge; thus, in phlegmonous erysipelas, when the matter is likely to be diffused extensively in the subcutaneous cellular texture, such practice is highly advantageous, and there is greater probability of the intervening spaces adhering. Occasionally, when an abscess has arrived at the condition of sinus, it answers well to make a counter-opening, as it is technically named, at some distant part from the original one, where the matter may escape more readily. If the abscess bursts spontaneously, the aperture may not be in the most favourable position for a free discharge, and sometimes the surgeon may find, when he has used the knife, that he has not selected the most dependent position: in other instances the matter may burrow afterwards, and in all such cases a second opening, at a more fitting part of the cavity or sinus, may bring about a speedy cure.
CHAPTER X.

SINUS. FISTULA.

If a free opening into an abscess be not made, the matter which will continue to be secreted from the surface, not readily getting vent, may collect in some dependent part of the cavity, burrow under the skin, and probably point elsewhere; or possibly the interior of the abscess will remain much the same as immediately after being opened, the surfaces may rub against each other, a constant secretion being thereby induced, and there may be little alteration for the better, even after the lapse of months. This condition and that termed sinus are nearly alike; the principal difference being, that in the latter there is a kind of canal, much longer than it is broad. Usually a sinus, or fistula as it is often named, is an irregular tortuous canal, with one or both extremities open, or possibly some lateral communication with the surface or elsewhere, having the interior covered with a membrane which continues to secrete pus. The openings into a sinus are usually small in proportion to the length of the canal, and often they close up so that the matter, no longer getting vent externally, accumulates, and expands the sinus in such a way as to give a resemblance to an abscess during its early formation. Suppuration near the anus almost invariably ends thus, constituting fistula in ano, and here the surgeon knows that his utmost skill can seldom prevent the formation of sinus: the abscess will not heal entirely. In other parts of the body, fistula will occur in spite of the utmost care; occasionally it is the result of negligence; and very frequently it arises from too small an opening being made originally.

An abscess in the condition above described, and a sinus, may be treated much in the same way: the cavity must be made to close, and a variety of methods may be resorted to for this purpose; all of them having for their immediate object the inducement of a new and perhaps excited action, under which the grand object of treatment is gained, viz., the complete reunion of the parts.

One of the simplest means of treatment is pressure, which is usually effected by a pad of lint held in its place over the space or sinus, by straps of sticking-plaster, or a roller; the surfaces are then kept steady, perhaps a slight adhesive action is excited, and so union occurs. Stimulating injections will probably accelerate the action. Sometimes these are used by themselves, of considerable strength. Such plans, however, fail but too frequently, often no favourable change being produced, whilst occasionally they are so far deceptive as to cause the orifice to close; but the deeper part remains in its usual condition,—matter still continuing to be secreted, which, after collecting in considerable quantity, will burst through the original opening, or make a new one for itself somewhere in the vicinity. And so affairs may go for months or for years, as is often exemplified in
the case of fistula in ano, unless there be some more active interference on the surgeon's part. In almost all such cases the best practic is to lay the sinus freely open with a probe-pointed bistoury, such as the blade represented in fig. 72. The point should be passed into any of the openings (for there may be more than one), and then the skin should be divided in all directions where there are spaces underneath. The point of the forfinger of the left hand should be freely used on these occasions, in tracing out wherever the matter may have burrowed, and also in breaking down the loose and flabby adhesions which are occasionally found in different parts of these cavities: it generally answers better than the common probe; and the additional pain, and, it may be added, apparent rudeness, will be amply compensated by the more certain cure that will be the result. When a patient is subjected to such a proceeding, it had better be done effectually, once and for ever. I feel assured that the want of success from using the knife on these occasions is from not attending to this circumstance. The most experienced surgeon cannot always be sure in what different directions sinuses may run, unless the finger be used as indicated above. Perhaps a single line of incision through the skin may suffice; but, in general, if the space be large, and the necessity for free exposure great, there need be no hesitation about notching the sides of the wound, and thus making a crucial incision. It has occasionally been the custom in modern times, to divide the tissues with a strong thread instead of a knife, a relic of ancient practice, which few surgeons of the present day seem to countenance, being more painful and less certain in its effects than the other; and being, moreover, a kind of return to that barbarous and do-no-better surgery of former years, which inculcated amputation by a similar process, viz., that of encircling a limb with a cord, which should be gradually tightened more and more, until the part below should drop off. Among surgeons of the present day in whose estimation this practice with the ligature obtains favour, I may name an authority so distinguished as Mr. Luke, of the London Hospital, who, during his active career in that institution, was in the habit of thus treating fistula in ano.

Mr. Marshall, of University College, has proposed the heated iron for similar purposes, and has brought the subject under notice at the Medico-Chirurgical Society, and elsewhere. A paper of his on this subject was published in the Transactions for 1851. He first introduces a platinum wire, which can be bent in any required direction, and then, by means of a galvanic battery, so heats the wire, that on the application of a little traction, it sears its way through such tissues as require division. In certain cases, when ordinary modes of treat-
ment fail to close a sinus, the heated wire may be legitimately resorted to. Hitherto the surgeon has been unable to do more than touch an orifice or point in such a way, owing to the slender body of metal getting so soon cold, but by this ingenious application of galvanism the whole extent of any long narrow fistula may be thus excited, and the plan seems to have succeeded under Mr. Marshall’s care, in a case of the sort which appeared incurable by ordinary means. In the “Lancet” for the 17th May, 1851, two cases of hemorrhoids and one of fistula in ano, are described as having been treated with the wire heated in the way alluded to. In these cases the wire was made to do the work of the knife, scissors, or thread, and to those who object to such means (some having the utmost horror of the knife, others of scissors, or of the thread), possibly this novel method may present some attraction.

I should myself prefer the knife for the operation for sinus or fistula, although sometimes, to comply with the peculiar views or fancies of some patients, I can see no reasonable objection to the proceeding above referred to. In using a cutting instrument freely in such cases, the bleeding is considerable; but a ligature, caustic, cautery, or other styptic, is rarely required, provided the operator has a moderate share of anatomical knowledge to guide him in making the incisions. The lint, with which the gap should be filled, applied with pressure if need be, will usually stop the effusion. Warm dressings, and occasional fomentations, should next be resorted to, and the treatment afterwards should in every respect, almost, resemble that required after the opening of an abscess, as already described. Should the wire or cautery be resorted to, of course a thin slough will be made on the surface, which must be treated with poultices, or such other dressing as may seem requisite to promote its separation.

It is not always that an old abscess, sinus, or fistula, can be thus treated, however, as for instance, the space below the skin may be so ample, that a reasonable surgeon would dread exposing so great a surface, as well as the indiction of a wound sufficiently large to open all the interior; or perhaps the sinus may run where he does not wish to make incisions, as in the face or neck of a young female, or possibly under some large blood-vessel, or other important part. In such instances, if a persistence in the mode by pressure and stimulating injections, above recommended, does not succeed, possibly the heated wire as above alluded to, or the introduction of a thread or seton, may have the desired effect. The presence of a seton for a few days will induce new inflammatory action, which may end, after its withdrawal, in the closing of the track. I have sometimes found this plan most serviceable; but it does not always succeed, and should only, in my opinion, be resorted to when the knife cannot with propriety be applied. The thread, which may be of hemp, silk, or worsted, and of a size proportioned to the calibre of the sinus, may be introduced by means of the common probe, such as seen at p. 11; the thread being attached to the eye, the point of the instrument should be passed through the subcutaneous space, and caused to pro-
ject where it is desirable to bring it out; an incision should then be made upon it,—a simple puncture will generally suffice to let it pass to the surface, when it should be seized by the fingers, drawn out through the wound, and the thread, which has followed its course, may be left, with ends of equal length hanging out of each aperture.

Although I have recommended the free use of the knife in the cases alluded to in this chapter, when other means will not avail, there are certain instances where this practice may not be necessary, or where something additional may be required; thus, a foreign substance,—any extraneous object that may have passed into the body, or a piece of necrosed or carious bone, may be the cause of sinus. In the first of these examples, probably the foreign body may be reached and removed without any particular use of the knife; and, if so, in all probability the sinus will speedily close. If necrosis be the cause, possibly the loose portions of bone may be removed by equally simple means; perhaps, however, a little additional cutting may be required, and this will be especially necessary in the instance of caries. The description of the operations for these purposes will be found in after parts of this work, and I need not say more at present on such subjects. It is impossible in every instance to remove, by such direct surgical or mechanical means, the foreign substances which may, by the continued irritation they keep up, prevent the closure alike of wounds, abscesses, or sinuses, and the appropriate treatment under such circumstances will be found in various parts of this volume.

CHAPTER XI.

EFFUSIONS ON SURFACES. HECTIC. SECONDARY INFLAMMATIONS AND DEPOSITS.

The preceding remarks on effusions or formations refer chiefly to such as occur in the textures of the body. When matter is discharged from surfaces, the plan of treatment, if the case be of a surgical character, is usually less difficult to decide upon, and less troublesome in its application. In such discharges from the vagina, for example, whether the result of gonorrhea or otherwise, astringent lotions may probably suffice to check the suppurrative action. If there is much active inflammation present, suppuration is often a relief, and therefore, at first, instead of checking it, the secretion ought rather to be encouraged by warmth, applied in some of the modes already described; but when the disease has assumed a chronic condition, astringents may be used with propriety; and here, too, there may be need of some alteration in the constitutional treatment. There is often much benefit in a change of air and of diet, which latter should be generous; and tonics, especially iron, may be additionally serviceable. In some of the mucous membranes, it is occasionally the custom to use strong astringent applications at the commencement of inflammation, before suppuration has actually occurred, by way of arresting all
SECONDARY INFLAMMATIONS AND DEPOSITS.

91
disease at once: in suppurative ophthalmia, for example, a solution of nitrate of silver, of the strength of ten or twenty grains to the ounce of water, has been used, and with the desired effect too; but the plan is by no means in general use. Similar practice is sometimes tried with good effect in the early stages of gonorrhoea in the male; but the danger of bringing on swelled testicle by thus suddenly changing the actions in the urethra, usually deters the practitioner from resorting to it.

Effusions in the serous and synovial surfaces frequently require surgical treatment, as hydrocele, aseites, hydrothorax, and also certain such affections of bursæ and articular surfaces. Sometimes these effusions consist of an excess of the natural secretion; at other times, the fluid seems a mixture of serum and lymph, or pus with serum or synovia. It rarely happens that pure pus is found in any of these cavities, although every experienced pathologist may occasionally have seen cases of the kind. In dissections of those who have died of acute peritonitis, pure pus is sometimes found as if it had been secreted from the serous surface: in the pleura, too, a similar occurrence may occasionally be noticed; but in general, when there is pure pus, its formation appears to have been preceded by the exudation of lymph, forming a new lining surface to the original serous membrane, in most respects analogous to that which forms the interior of ordinary abscesses.

The treatment of many of these affections will be particularly considered afterwards. Here, however, I may state, that it is usually conducted according to the methods previously described for inflammation and abscess. At first, if the effusion seems the result of acute action, the violence of the disease must be allayed by such local and constitutional remedies as have already been described, and by such specifics as may be known,—as, for example, cathartics and diuretics, in aseites, or colchicum in what are usually called rheumatic effusions into joints; then, as the action becomes chronic, such plans as may be supposed to excite absorption may next be used, and should these fail, the propriety of giving vent to the fluid may be taken into consideration. On the latter point there need be little hesitation on some occasions—as in the case of hydrocele, whilst in others—as in hydrothorax, the circumstances of the ease should be well weighed ere the surgeon proceeds to open such a large serous surface.

Long-continued and profuse suppuration is almost certain to end in heetie, a kind of fever with which the physician has perhaps more to do than the surgeon, for if he cannot arrest the secretion by removing its cause, changing the action, closing the abscess or sinus, or amputating the diseased part, then he can only trust to those means which a knowledge of practical medicine, or common prudence, may suggest.

Dr. Norris of Philadelphia has, in his American edition of this work, appended an admirable chapter on "Secondary inflammations, and deposits of pus after injuries and operations," in which he points out the frequency of such occurrences after amputations as well as other injuries. The lungs and liver are more frequently affected in this way than any other organs, but there is scarcely a region, organ,
SECONDARY INFLAMMATIONS AND DEPOSITS.

or tissue, which may not suffer. The slightest injury in one part may so affect the usual tenor of the system as to induce some violent and perhaps fatal inflammation in another and distant portion of the body. The patient may in one instance be carried off ere the development of any of the usual consequences of the affection, while in another case there may be effusions of serum, lymph, and pus. These occur very frequently in the serous or synovial surfaces, as well as in parenchymatous structures. In one example there may be a large collection of serum or of pus, in another numerous small abscesses may be scattered in all directions; there may be evident marks of surrounding inflammation; while, again, in some instances, in a large joint, for example, the slightest trace of preceding disease cannot be detected. Often the inflammation, suppuration, and lymphatic effusion may be connected with the medullary membrane of a bone or a large vein; and the doctrine has been held by Cruveilhier and others that these parts are generally more or less involved in such secondary affections.

The constitutional symptoms in these cases generally at first denote a high degree of excitement, but they soon indicate a typhoid condition, and death is the usual result. The symptoms of low fever often come on so insidiously that the practitioner is astonished that he has in a manner overlooked the coming danger until such a state has given the first serious alarm. Many imagine that these symptoms are occasioned by the presence of pus globules in the blood, and that the secondary deposits are the results of the separation of the pus from the circulation. In my remarks on the premonitory symptoms of suppuration I have made some allusions to shiverings as indicative of this result. Rigors are of common occurrence in the early stages of the condition at present under consideration, and if with these there be a quick, small pulse, a dry, brown, furred tongue, a sunken, unmeaning eye, a dry skin of a dingy yellow colour, there is much reason to dread the worst. The wound, in such a case, if it be still open, will have ceased to discharge; there may be constipation in the bowels, or possibly diarrhoea, especially in the latter stages of the affection; there may perhaps be difficulty of respiration, pain, and other symptoms indicative of serious derangement within the chest, or there may be reason to apprehend mischief elsewhere. In short, the state of the system differs little from that familiar to the physician in the worst forms of typhus fever, and on that account I may decline entering further on this part of the subject.

It is well known how futile the practice of physic is in such instances, and the same must be admitted for that of surgery. Depleting means should rarely be employed. Velpeau, Norris, and others have reprobated the practice, and I cannot say that I have ever seen benefit derived from it. In a purely inflammatory affection of the lungs, which may to all appearance have been induced by an injury in some distant part, or possibly by the deligation of some large artery in the neck, the use of the lancet may perhaps be not only justifiable, but of much value: yet should there be typhoid symptoms present, the practice is more likely to do harm. But the discussion of such
GRANULATION. CICATRIZATION.

matters belongs more properly to the physician; and as a surgeon, then, I have little to say regarding the purely surgical treatment of these secondary inflammations and deposits. In such cases it will at all times be a happy omen should the wound begin to discharge again, and such local treatment should be resorted to as is deemed most likely to encourage this favourable change. In the event of a collection of fluid forming anywhere within the surgeon's reach, a question as to giving it an exit may arise, and, generally, his knowledge of the practice of physic as well as of surgery—which must be gleaned from more extensive sources than a few pages on the subject—be the author of them whom he may—must guide him in the treatment of these most formidable cases.

In recent times the above subjects have been referred under the titles of "pyaemia," "blood poisoning," and so forth; but with the exception of new names, including "sweet breath," "cow's breath," &c. &c., I know of little practical difference between what is called new and what was recognised fifty years ago.

CHAPTER XII.

GRANULATION. CICATRIZATION.

In wounds where union by the first intention does not take place, the term granulation is generally used to denote that peculiar process which is always present in such cases, ere the open surface closes. The lymph, which is effused as the effect of the inflammation in these instances, becomes organized; and the surface of the wound, which at first presented the ordinary tissues of the part, is covered by innumerable small elevations, more or less red, according to their age and condition, which are technically called granulations. When a wound heals by the second intention this process must ensue: it is the partial contraction and glazing over, as it were, of the granulations which constitute cicatrization, or healing, and no union of an open suppurating sore can occur until granulations are present, and close over. Granulating sores are frequently the result of abscess. It will happen sometimes, that when an abscess has been opened and completely evacuated, its sides, falling together, coalesce and adhere by the first intention, but often a suppurating sore remains, on whose surface granulations form, and as the sore heals, cicatrization occurs,—the two latter terms being in a manner synonymous.

When granulations are healthy, they are disposed to heal spontaneously, and indeed often do so. In some cases the surgeon can scarcely flatter himself that he confers the least benefit, but in other he has it in his power to aid nature materially. The term "healthy" is usually understood as denoting that condition of granulations in which there is an evident tendency to cicatrization: if, when they are in this state, any different action occurs, the healing process cannot go on at the time, nor until the healthy action is again present; and here it is in the power of the surgeon, in many instances, so to caution
his patient against irregularities, to dress the sore, to support the parts, and to give them a good position, that he may exhibit many of the best qualities of his profession.

I need scarcely refer to what the irregularities may be, and will only remind the young surgeon, that the nearer he keeps his patient's constitutional health to what may be deemed the natural standard, in each special case, the greater is the probability that the local affection will be cured. The dressings for such a sore need be few in number, and ought to be of the simplest kind. It is not easy to convince a non-professional party, that the usual applications in these cases have no remarkable specific effects on a sore: thus arises the popular credulity in nostrums, and the rich harvest for "The poor man's friend." I fear that professional men often take too much credit to themselves, or assume it for their applications. They overlook the remedial powers of nature in such cases; hence, perhaps, the opposite opinions regarding the effects of certain agents, and the vast variety of remedies in use.

It may be a question with the young practitioner,—when granulations are healthy, and how he is to know that they have assumed this condition? When the surface of a sore becomes of a bright red hue, when the surrounding swelling and other marked symptoms of inflammation subside, when the open space diminishes in size, and the circumference seems of a light blue colour, he may feel satisfied that the granulations are in this state. If the sore is now accurately examined with the naked eye, or with a glass, the surface will be observed to be covered by numerous small irregularly rounded points, red with arterial vascularity, which are the granulations. If no retrograde action takes place, such surfaces have invariably a tendency to contract and heal, and will do so, provided the surgeon takes due care of the sore. The continued use of a poultice, or of water dressing, may be sufficient, or, perhaps, of some simple ointment, such as the spermaceti,—these having the sole effect of keeping the surface moist, and thus preventing the matter which exudes from it becoming hard, and a source of irritation. Often, however, without any perceptible cause, the healing action does not seem to progress, and perhaps the granulations become somewhat pale, larger, and of a gelatinous flabby aspect; at this time a change of application may be of service, a slight stimulus will induce a further cicatrization, and at last the desired end will be accomplished. Here, then, the surgeon, as it were, assists nature. The usual stimulants on these occasions are solutions of acetate of lead, of the sulphate of zinc or copper, or of the nitrate of silver,—the latter, or the preparation of copper, being occasionally applied in their solid forms; ointments of the nitrate, or of the red oxide of mercury, of the oxide or carbonate of zinc; and a variety of others in the form of red, black, and blue lotions or washes, which require no particular notice here.

A lotion, when used on these occasions, is applied either cold or lukewarm, and if oiled silk is put over the moistened lint with which the sore is usually covered, it soon acquires the natural temperature
of the part. Instead, however, of keeping the surface constantly covered in this manner, the granulations may be only bathed at each dressing, after the lapse of twelve or twenty-four hours.

I may, perhaps, not be correct in designating all the means above alluded to as stimulants; but, at all events, an occasional change from one of these to some other, produces, in general, a favourable alteration on the sore. Such local applications resemble, in their effects, the action of certain purgatives, to which the bowels become at last, after continued use, so much accustomed, that the peculiar action of the medicine cannot be produced except by increased doses, when, probably, a smaller quantity of another remedy may have a powerful influence. So it always is with lotions or ointments, some of which may actually cause pain when first applied, but in the course of a few days may fail in producing any effect at all; although if another application of moderate strength be used, a new action seems to take place in the sore. Hence, then, the advantage of changing dressings from time to time.

The dressings may merely be laid on the surface, and retained by means of a loose bandage, but sometimes it is highly beneficial so to support the neighbouring parts—so to approximate them—that there shall be no drag upon the granulations, and that every facility shall be given to the process of contraction, which takes place in cicatrization. A roller properly applied, or adhesive straps (which usually act as gentle stimulants, partly from pressure, and partly from the composition of the plaster), or probably both combined, may produce the desired effect.

Although in most instances it is highly desirable to produce contraction of granulations so that the cicatrix shall be of the smallest possible size, there are certain examples where great precaution should be used, lest the contraction should be such as to cause inconvenience or even deformity. In the cicatrization of severe burns, for example, parts of the body may be unnaturally drawn towards, or fixed against, each other, as is often seen in the hands and fingers, between the arm and chest at the axilla, and between the skin of the chin and that over the upper end of the sternum. I believe that more may be done to prevent these occurrences by proper attention to position at first, than by attempts to improve the state of the parts by subsequent operations. It is well to bear in mind, too, that contraction does not cease as soon as cicatrization has occurred: it will often go on to an amazing extent afterwards, and this may be for good or evil, according to circumstances. To continue the example of burns; if, when cicatrization on the surface seems complete, the patient is allowed to carry the part in such an attitude as he finds most convenient or agreeable, vast deformity may be the result, although the surgeon may have bestowed great attention during the period of granulation. There must be few practitioners of experience not familiar with such examples. A patient was under my care with a large granulating surface in front of the elbow, resulting from a burn: as cicatrization went on, I kept the arm in an extended position, having no fear of a stiff joint; when the
process appeared completed, the patient was allowed to keep the extremity in any attitude he chose, and whilst out of bed he bore it in a sling with the elbow bent at a right angle; in the course of a few days, the cicatrix became prominent, forming a band between the lower end of the arm, and upper part of the forearm, evidently preventing extension: a little force, however, was sufficient to counteract this evil tendency; the straight position was again resumed, but it was not until after several similar occurrences that the disposition to contract seemed to cease. But more will be said on these matters in another part of the work.

With regard to attitude, it may be deemed an established rule, that the affected part should always, if possible, be kept on a level with, or above, the rest of the body. If this be not attended to, the healing process goes on much more slowly (if it goes on at all), and hence, then, the advantage of keeping a person in the horizontal position, who has a sore on the leg. These rules of practice will be more fully illustrated in describing the treatment of injuries and ulcers of the lower extremities, as well as of other parts of the body. I may state, however, that there is a combination of benefit in rest, position, or attitude, and support by straps, rollers, or other convenient apparatus, which is not always taken into due account. For instance, if a person with a healthy sore on the leg, who has been kept to his bed, is allowed to get up and walk about, the sore is almost certain to retrograde, unless some support be given to the tender vessels in the equally tender granulations: they will burst and bleed on the surface, or effusion and infiltration of serum in the organized lymph will speedily occur, and days or weeks may elapse ere the part resumes the condition in which it was when the patient was first allowed to get out of bed.

CHAPTER XIII.

ULCERATION.

The process of ulceration, which is usually deemed a product or consequence of inflammation, is always a source of much vexation to the surgeon, often of great annoyance to the patient, and not unfrequently of the utmost danger. It is one over which the practitioner has but little control; it usually causes much pain and alarm, and occasionally opens important organs, as the stomach, intestines, or large blood-vessels, so as to cause speedy death.

The terms ulcer and ulceration seem often to be confounded with each other, although in the proper application and acceptation of these words, there is really a great difference. Ulcer is a generic term applied to all sorts of sores, more particularly to those which are on surfaces, but in many such, ulceration has never at any time been present. A person who has sores on his legs within a few days of
ULCERATION.

97

healing over, is said to have ulcers, and the term is perfectly understood in some respects, although the difference between these surfaces at the commencement of the disease, and towards the end, is not always sufficiently appreciated. In the early stages nature seems determined that the affection shall spread, whatever opposition the surgeon may offer: parts visible to the eye at first, in a few days disappear by the ulcerative process: the sores go on increasing in size so long as the unhealthy action continues, but towards the latter stages nature seems just as determined to heal them up again. At first, ulceration is present; latterly, the process of healthy granulation: there is a sore, or ulcer, but instead of any excavation, such as is seen in ulceration, there is actually an effusion of lymph on the surface,—a kind of addition caused by nature, instead of a loss.

Hitherto it has been the custom to account for the loss of substance in such cases by what Hunter termed the ulcerative absorption, but it is supposed by more modern pathologists that the destruction of parts is chiefly the result of disorganization and softening of portions of the affected tissues: the parts so changed being swept away in the puriform discharge.

The term ulcer is usually applied to a healthy granulating surface, such as that which is present in a wound healing by the second intention,—a stump, for example, treated in the Continental fashion, without bringing the surfaces into apposition at first; yet here, it may be remarked, the process of ulceration will, in all likelihood never be present at any period, from the infliction of the wound until cicatrization is complete.

In most instances of ulceration there seems to be a deposit of lymph between the affected surface and the parts immediately underneath, and hence, when vessels of moderate size are destroyed by this process, there is a security against hemorrhage. Sometimes, however, this effusion does not occur, and then the ulceration is most dangerous; and sometimes the ulcerative process removes the lymph that may have been effused: of both of which examples the secondary hemorrhages which occur after amputations and operations for aneurism give too frequent proof.

Ulceration may go on in any texture and in any part of the body. On the skin and on the mucous membranes it is seen in a variety of forms; and it occurs frequently in articular surfaces, cartilages, bones, and blood-vessels. Generally it is attended with a secretion, or formation, of pus, although there are instances in which it seems to occur without this accompaniment. Where pus is present it is usually small in quantity, thin and watery, of a pale colour, though occasionally tinged with blood, especially in the early stages of the disease. The matter will vary in aspect and in amount according to the condition of the sore and the nature of the dressings; and there is no better test of the improvement of an ulcer than the approach of this fluid to the semblance of "laudable pus."

The management of particular kinds of this disease will be best exemplified in after parts of the volume, but here it may be stated
generally to consist in such measures as are supposed to arrest its progress and bring on a healing action. The usual treatment for inflammation, constitutional as well as local, seems most applicable, whether the ulcerative process is going on externally or internally. When all the symptoms of inflammation are well marked, as most frequently they are, abstraction of blood, locally in particular, fomentations, counter-irritation, and other remedies already referred to, may be of service; and where the disease seems to be of a specific nature, as in poisoned wounds or sores, from syphilis or other causes, the destruction of the affected surface with caustic, and the internal exhibition of mercurv, or other medicines, may bring about a more healthy condition.

CHAPTER XIV.

GANGRENE. MORTIFICATION.

Gangrene is usually understood as that condition in which a part still possesses a certain degree of vitality, and where there is a possibility that the alarming state may pass away. Mortification is the complete death of the part, and the word is generally used with reference to a considerable portion of the body—as when the whole thickness of a limb is in some measure affected. The term "slough" is in common use to denote the death of a portion of the soft parts; that of "exfoliation," or "sequestrum," is applied to a dead piece of bone. The conditions of gangrene and mortification, whether these be the result of inflammation or otherwise, usually demand much care and attention on the part of the surgeon. In many instances of inflammation, the disease runs a regular course—from a mild form to one more severe, which then assumes the condition of gangrene, and ultimately that of mortification. In other examples it is difficult to discover any marks of severe inflammation previous to either one or other of these events; and, indeed, in some kinds of mortification, it is impossible to say that this affection has been present at any period, as in that which occurs in old age, or in certain examples of disease of the heart; even in some other cases, of deep interest to the surgeon—the ligature of a main artery, perhaps—it may be doubted (perhaps even not so by some), whether inflammation has ever been present in the affected part.

For the purpose of illustrating the state of gangrene, I shall take an example of a fracture of the lower ends of the bones of the leg, perhaps compound, with great contusion and laceration; in such a case the certain result is inflammation, and that too of a high degree, in consequence of the severity of the injury: here all the symptoms of this disease will be well marked; pain, heat, redness, and swelling, will each be conspicuous. If gangrene threatens, the swelling will probably attract most attention; perhaps the pain and feeling of heat
may then be less, and, in all likelihood, instead of the colour being a bright red, the surface will assume a bluish aspect; it will perhaps, too, feel to the surgeon colder than it may have been, and the cuticle may be elevated at various points by effusions of serum, technically named bullæ, phlyctenæ, or vesicles. At such a time, if the part is touched by the fingers, it will feel tense and crepitating, for now there will be air in the textures. In such a case the constitutional symptoms are probably of less moment than the local, as denoting the extent of the mischief. At first there will be the usual constitutional indications of severe local inflammation; latterly the pulse will sink, and become irregular; the skin will be pale, cold, and clammy; the countenance will assume an anxious, haggard appearance; there may be vomiting, hiccup, and delirium. Under such circumstances there need scarcely be a doubt that gangrene is present, and it is usually to such a case that the terms acute, humid, and traumatic gangrene are applied. Sometimes, however, when no such injury or evident cause of derangement is present, the leg and constitution will assume similar conditions as those last referred to; after ligature of the femoral or iliac artery, for instance; yet, as I have already stated, in such a case it may be doubted if inflammation has ever been present. The condition may be equally acute, the limb equally humid; and though it may in justice be attributed to the wound and obstruction of the artery (the latter without doubt), yet it cannot with propriety be termed traumatic. It is not my object here, however, to argue such points, but by way of practical contrast I shall now sketch another form of disease. A person may have disease of the heart, dropsy, and anasarca, or possibly none of these affections may be observable; the points of the fingers or toes may assume a blue colour, will be painful, cold, and perhaps slightly swollen, yet the practitioner cannot entertain the idea that inflammation is present; by and by the points of one or more of these members will become of a darker colour, at first of a leaden aspect, then of a deeper gray or ash colour, and ultimately of a brownish black; all heat will cease, excepting that derived from contiguous sources, and to all appearance, as in reality, the part will have become dead, and at the same time shrivelled up. I shall take another example, one perhaps of more interest to the surgeon: a person receives a deep wound above the wrist, on the inner side of the fore part of the limb; the ulnar artery is divided, and afterwards secured by the surgeon when he dresses the wound; in the course of a few days the little finger is discovered to be cold, leaden-coloured, and destitute of sensation, and in a few days more vitality ceases. Such examples as these are in contra-distinction to the ease of injury of the leg first taken for illustration, termed dry gangrene, or, properly speaking, dry mortification; but it is often difficult to draw a clear distinction between the two kinds. Dry gangrene—senile gangrene, as it has been called—is generally seen in advanced years, the result in all probability of deficient circulation; but it may be seen at any period of life, as is also the case with the humid form of the disease; and
it will be observed that any kind of gangrene, or rather mortification, if allowed to remain sufficiently long on the body, is sure to become dry.

In gangrene the general object of treatment is to restore, if possible, the healthy actions, and so avert the impending death of the part, which is very likely to ensue if a favourable change does not occur. In mortification, or sphacelus (for the terms are synonymous,) the principal indications are to protect the remaining parts from destruction, and to relieve the system of that portion which has become dead, as in this condition it can only be a source of irritation and continued disease. The part which has lost its vitality may be a portion of skin, mucous membrane, tendon, vessel, bone, or other individual texture, singly and only to a small extent; possibly several of these tissues may be involved, or all the textures in a member may be in this condition at one and the same time. It will be evident, then, that the treatment must be varied and regulated in accordance with the nature and extent of the affection in each particular case.

From what has been already stated, it may be observed that the cause of these conditions is often, in a great measure, beyond the influence of the practitioner; but in many instances, and where the inexperienced might least suppose it, he has great facilities in obviating the worst results. Thus, if in the treatment of fracture of the lower extremity the heel is allowed to rest on a hard mattress, the pressure on the skin, by the weight of the limb and foot may produce mortification,—a slough as large as a half-crown may form. If the surgeon is on his guard, and, at the first alarm, so adjusts the pads and splints as to take off pressure from the part, no such event will happen. Again, if in severe inflammation of the scrotum, accompanied (as it usually is) with copious effusion of serum, the part be not well suspended, and kept rather above the level of the pelvis, a slough in the skin is very likely to occur, and the same thing may happen in extensive cedema of the lower extremities. Here, too, the surgeon may, by attention to position, do much to avert the occurrence of this disease.

Severe cold is a well-known cause of gangrene and mortification, especially if warmth be applied suddenly when the temperature is below the natural standard. The experience of Larrey in Russia, on the latter point, gave ample additional proof of this well-known fact; and hence, then, the propriety of restoring warmth to the parts gradually, by friction and otherwise. Intense heat is a frequent source of these conditions, as exemplified in scalds and burns. Sometimes a bandage may be too tight around a limb, when it will produce swelling in the part below, and if not attended to, even partial death; the tightness of the orifice of the prepuce in paraphymosis may produce this, although I believe it does so more rarely than some apprehend; and the stricture in or about the neck of a hernial sac is a fertile source of these affections. If a tourniquet is kept long upon a limb, as is sometimes done in hemorrhages, cedematous swelling is sure to come on, and mortification would be a certain result were the constriction continued.
GANGRENE. MORTIFICATION. 101

The above are all palpable examples, where a little surgical skill may be of service, but other instances are less controllable. In the example of gangrene, resulting from severe inflammatory action, as in the kind termed traumatic, there is less probability of arresting the progress of the case towards mortification. All such measures as are likely to subdue inflammation must be actively resorted to: here some pin their faith upon cold applications, whilst others are equally sanguine in the efficacy of warmth. For my own part, I should place most reliance on such measures as have already been recommended for the treatment of acute forms of inflammation, more particularly if the affection be very prominent on the skin. Above all, I should resort to incisions, chiefly on account of the relief to tension which they would produce, by giving exit to blood, serum, air, and pus; for in some cases both the latter may be present. This last mode of treatment will not arrest the disease in all instances, but it may produce wonderful effects in some. If proper cases for its adoption be selected, such as where there is great swelling and tension, (as in severe forms of erysipelas, in which gangrenous inflammation occurs,) I cannot imagine that incisions will at any time do harm. The practice may appear harsh, and so indeed it is; but it should be remembered that it is applied to save the vitality of a portion of the body, the death of which, whether large or small, may probably involve the life of the patient. An excellent example of the advantages of this kind of practice is afforded in the instance where the urethra gives way behind a stricture; here the urine gets rapidly into the cellular texture of the scrotum: high inflammation succeeds, and, if the surgeon does not interfere properly, gangrene and mortification are the inevitable results. But if a free exit to the urine be allowed, through one or more incisions into the swollen and already perhaps dangerously inflamed parts, the irritating cause is, as it were, removed, and the formidable event is averted, or at any rate more limited in extent; and here, too, it must be observed, that the cause of the disease could be got rid of in no other way.

When the vital powers are deficient from external causes, as in the case of frost-bite, these may be gradually restored by judicious means; and in instances arising from the obstruction of a main artery, as after ligature, in which case there may be sudden alternations of temperature, attention to the latter circumstances may be of service. When mortification arises spontaneously, or from some apparent internal cause, over which the surgeon has no control, he cannot expect to avert the disease, but he may, nevertheless, be of service to the sufferer; for here, as in other instances, after sphacelus has actually taken place, he may apply his skill with excellent effect: indeed, it may be truly said that, in many cases the efficient treatment only begins after this period.

In the early stages, any constitutional treatment, further than what may be required for the particular form of fever present, will have but little influence over the local disease. Instead of the high symptomatic fever, which is usually present in the ordinary kinds of severe local
inflammation, there may be a depressed state of the system for which stimulants may be extremely useful,—as camphor, ammonia, wine, or spirits; and these, if the patient’s stomach will bear them, will seldom prove amiss, after sphacelation has actually taken place. The free use of opium, by itself or combined with calomel, will often be of much service in alleviating the extreme suffering from local pain, which latter is often most distressing to witness, particularly in those instances occurring in advanced years, from disease of the heart or blood-vessels. At one time the Peruvian bark was deemed a specific for most forms of this affection; but so far as I am aware, no faith is now placed either in it or quinine, further than as an excellent form of tonic in the latter stages of treatment when the patient is convalescent. The diet must be regulated in these cases in accordance with the apparent effect on the system. In some it must be rather generous, while in others, especially in elderly patients, and in chronic forms of disease, it may seem best to administer both food and stimulating fluids in moderation.

When a part of the body has in reality become dead, the first object of local treatment is to promote its separation from the living, a process which is usually performed by nature, by that kind of action which Hunter named Disjunctive Absorption. The more rapidly the separation is effected the better. In general the stench, being very offensive, gives additional inducement to get rid of the putrid mass. Excepting in particular cases, the surgeon should never attempt to hasten the process of disjunction by mechanical means. The inexperienced will often wonder why the knife or other cutting instrument is not used on these occasions; but unless it be to divide the skin over a slough of cellular texture, or the soft and hard parts around a dead portion of bone, so as to allow of either being lifted away by the surgeon, or thrown from the surface by nature, such interference should seldom be resorted to. At first there may be some difficulty in appreciating the extent of the disease; and, latterly, when its limits have in a manner been defined by the chink, fissure, or line of separation, (“de-marcation” is the technical word), which forms between the dead and living tissues, there seems no good reason for interfering with the natural process, as the after-part of the cure is not expedited thereby. Sometimes, when a slough has become very loosely connected to the adjacent textures, a portion of it may be cut away with scissors, but on no account should the living parts be touched. If these be cut, the wound will give pain, and must go through various stages of inflammation, ere it arrives at the condition of the surrounding surface, where separation at various points may have previously occurred. Often, I believe, it is best to trust the process almost entirely to nature, and merely to apply some simple ointment, poultice, or soothing fomentation; but sometimes there is an advantage in local stimulants, as the disjunctive absorption seems to be accelerated by them. Among the soothing remedies, warm water, warm decoction of poppies, of hemlock; solutions of acetate of lead, with or without opium, bread poultices made with one or other of these fluids, the linseed poultice,
the hemlock poultice, and such like, are usually resorted to; and as stimulants, a vast number of means have been used, varying in quality from the moderate excitement of a mixture of a resinous tincture with water, to the destructive agency of the potential or actual cautery.

In general, I imagine that gentle stimulants only should be used. It ought to be remembered that their influence is intended solely for the living parts: if too much excitement is produced by strong stimuli, possibly gangrene may be encouraged, and, at all events, more pain is occasioned by their use than the circumstances warrant. No harm can result from the application of caustics or the heated iron, provided the living parts are not touched by them; the stimulus of their qualities conveyed to these parts, through the medium of the slough, may induce favourable excitement in the living textures; but when they touch the latter, they will kill, and thus produce further mischief. It is good practice, on many occasions, to rub the surface of a sloughing, ill-conditioned, languid ulcer, freely with caustic, or even with the heated iron; but here, be it remarked, there is a slough already present, or it is intended to convert the surface into one by this direct and killing measure, for in the latter case the application seems to have the effect of causing nature to bring the disease to a crisis, as it were, and no longer to leave all the parts in a half-dead state, the surface being thus killed outright, and the adjacent vessels excited to a more healthy action. It is customary in the instance of carbuncle to cut freely into the gangrenous and mortified textures, but the object of doing so is apparently not understood by some. The incision in such cases should never penetrate beyond the actual gangrene and sphacelus: it should, however, be close upon those parts where the separation is expected to take place; for, under these circumstances, stimulating applications influence the living tissues much more readily than when conveyed through the whole thickness of a slough.

Stimulants in these cases are most commonly applied through the medium of poultices and lotions. A bread and water poultice, with a little tincture of myrrh, oil of turpentine, port wine, or such irritating fluids, poured over its surface, may suffice, or the common fermenting poultice may be used with benefit. Sometimes resinous ointment, by itself, or mixed with turpentine, is spread over the surface of such poultices. At the periods of dressing great care is taken to wash away all foul discharges, and no fluid answers better for such purpose, I think, than a mixture of tincture of myrrh and water, of the strength of half a drachm, or a drachm to the ounce, or according to the stimulus supposed to be necessary. Of late years it has been much the custom to use solutions of chlorine or of carbolic acid for such purposes; and the solution of permanganate of potash has recently been much in requisition, chiefly, however, to correct the offensive smell of the slough.

By such means, and by time, a slough will at last become entirely detached, and may then be lifted away, or if it be left by a few shreds only, these may be cut across with the scissors, and when the large mass has been removed, the small remaining portions of these shreds may be left to separate afterwards. The surface, at the period of the
removal of a slough, is usually covered by healthy granulations in-
clined to heal over, and no particular treatment is required further
than that already referred to in the chapter devoted to granulation and
cicatrization.

Perhaps the most troublesome cases of partial mortification which
the surgeon has to deal with, are those which occur over the sacrum,
in persons who are long confined to bed from fevers, chronic diseases,
or fractures. As pressure seems in all such cases to be the immediate
cause of the affection, the exposed parts, such as the skin on the back
of the pelvis, over the prominences of the seapule, the great trochanters,
and the heels, should be defended by soap plasters spread on felt; and
when, unfortunately, sloughing occurs (or ulceration, for, as in many
respects the conditions are analogous, the treatment of either case
should be nearly alike), poultices will, besides their other good
qualities, act as soft cushions for the injured parts, and if a water bed
(Dr. Arnott's) can be procured, it will be found of the utmost utility.

CHAPTER XV.

QUESTION OF AMPUTATION IN GANCRENE AND MORTIFICATION.

The remarks in the preceding chapter are applicable chiefly to instances
of partial affection of some region: but it will happen sometimes that
the gangrene seems so extensive, in either the upper or lower ex-
tremity, or that mortification has committed such ravages, as to preclude
the hope of saving the limb, or even the life of the individual, if such
a source of irritation is allowed to remain. The surgeon will seldom
do his duty properly here, if he leave the case so much to nature, as
in the instance of a partial slough; for, although there is ample ex-
perience to prove that a portion of a hand or foot, fore-arm or leg,
may drop off, or that either member may be separated at its articu-
lation with the trunk, by the disjunctive absorption, it is equally
certain that the work is done in a tedious, painful, and unsatisfactory
manner. Months may elapse ere a part is entirely separated; and
when this has at last occurred, months more may pass over ere the
sore cicatrizes. There cannot be a doubt that the surgeon is justified
in many of these cases, in performing amputation, and the only dif-
iculty in some of them is to determine the proper period for such a
proceeding.

In the instance of spreading gangrene, as has already been stated, it
is difficult, if not impossible, to say where the disease is to end,—where
there is to be a separation between the dead and living parts,—and
hence it has been the prevalent custom to wait until a line of demar-
cation has formed, though, from the examples of Larrey, Lawrence,
and some other modern surgeons, the practice of operating at an early
period has been strongly advocated. Although educated in these latter
doctrines, and strongly prepossessed in their favour, I feel bound to say, that, after having acted upon them repeatedly, and seen others do the same, the success has been very different from what I anticipated. I have in my recollection six cases in which I amputated during spreading gangrene, four times in the thigh (one of them being for a simple fracture of the leg, another for compound; both close upon the ankle; the third following spontaneous obstruction of a popliteal aneurism, and the fourth after ligature of the femoral artery for a similar disease); once (being the fifth) in the leg for severe lacerated wound of the foot, and once (the sixth) at the shoulder-joint for extensive injury of the arm. None of these ultimately survived. I might possibly in future resort to a similar practice, but should feel greatly inclined to wait for a line of demarcation, although even here I should not be very sanguine as to the result. Numerous cases might be brought forward, however, to prove the success of such practice, yet I believe that, in many instances, the surgeon will best show his judgment, by amputating, in severe injuries, before sufficient time has elapsed for gangrene to come on, or by waiting, in the event of such an occurrence, until it is seen how far, and to what degree, the affection is likely to proceed, and, in addition, to what extent the constitution sympathizes with the local disease. The latter circumstance is, indeed, often remarkable; but whether it is from the wound or the gangrene, it is difficult to say. I once saw an amputation in the leg performed by a surgeon of great experience, for a severe compound fracture: the calf of the leg, when the incisions were made, was in a slightly suspicious condition, but not sufficient to deter from selecting this part for the operation: unequivocal gangrene, however, attacked the stump, and within eight-and-forty hours amputation was performed in the thigh: again the disease appeared in the stump, and at the same time in the skin over one of the scapulae, where there was no suspicion even, that the slightest injury had been inflicted. Although I am satisfied that the operator did what the best rules of surgery dictated in this case, it is nevertheless exceedingly probable, that if delay had been given, in hopes of a line of demarcation forming, the condition near the shoulder would have been sufficient to have deterred from an operation at all.

If amputation during gangrene be decided upon, a question may arise as to the site of the operation. In the early stages, when it is impossible to determine how far the disease may extend, the incisions should, if possible, be made in a part where there is no indication of disease—even the slightest swelling or discoloration should induce suspicion. Dr. Norris has advised that "a joint had better be interposed between the injured part and the point of incision;" but I cannot here see any good reason for such a practice excepting as regards distance,—for a joint can evidently have no influence in checking the progress of a disease which spreads solely along the skin and other soft parts; and it is worthy of remark that in three of the cases out of the six above alluded to amputation was done in the thigh while the gangrene began in two of them in the lower part of the leg, and in the
other actually on the foot. If the affection has already implicated the
greater part of the member, the proceeding must then be effected close
upon the trunk—possibly at the shoulder; and although the prospect
is always most unfavourable when the knife is used upon parts already
inflamed and swollen—perhaps gorged by infiltration resulting from
diseased action, the surgeon need not utterly despair, for even then
success may result, as was the case when Sir William Lawrence am-
putated at the shoulder-joint under such circumstances. Every ex-
perienced practitioner must have seen examples where wounds in parts
so affected have healed most kindly,—such union, however, being, as
might be expected, chiefly by the secondention. The incisions
occasionally required in severe forms of erysipelas are examples of the
kind.

If the line of demarcation has become visible, then the operator will
choose the site of his proceedings chiefly with reference to the forma-
tion of a proper stump. He will of course cut above the line on the
skin, but ought to bear in mind that possibly the affection may have
extended further up in the subjacent textures; and on that account
he should be cautious both in his diagnosis and prognosis.

It will often happen, in spreading gangrene and also in mortification,
that the surgeon does not feel warranted in resorting to amputation;
yet, such is the tenacity of life in some individuals in the latter affec-
tion, that a large portion of an extremity may be converted, after the
lapse of weeks or months, into a shrivelled, dry, black mass, attached
to the body only by means of bone, which undergoes disjunctive ab-
sorption more slowly than the soft textures. In such a case it will be
but charity to assist nature with the saw, by applying it close to the
living part, where, if no dead bone be left, granulations will spring up,
and a tolerable, nay often an excellent stump will be the result. It
may sometimes be a question in such cases, whether it will be best to
cut in the line of demarcation, or perform a regular amputation a little
higher up; the latter should certainly be preferred in some instances,
although, as a general rule, particularly in persons advanced in life and
of debilitated constitution, I believe it will be best to follow the indi-
cations of nature, and confine the manipulations to the parts where
separation is already in progress.

CHAPTER XVI.

HOSPITAL GANGRENE. PHAGEDÆNIC GANGRENE.

Such a disease as that once familiarly known under the name of Hos-
pital Gangrene is now rarely seen, although from time to time, both in
hospitals and in private, cases are met with, which resemble in many
respects those of former years, when the disease committed such ravages
among our soldiers and sailors, and when in civil hospitals also, so
great was its prevalence and promness to attack all open surfaces, that it became altogether impossible to calculate with any degree of certainty on the results of surgical practice. It rarely happens now-a-days that a slight abrasion of the skin, or the wound of an amputation, is attacked with sudden and severe inflammation which speedily assumes a gangrenous character, and then rapidly terminates in mortification; yet such cases do occasionally occur, although not with the frequency of former times, when, as was said of the Hôtel Dieu, a student might learn how to perform amputation by seeing it done on the living body, but could never learn how to treat the stump from the same field of observation, as the patients operated on invariably died of this destructive malady.

The term Phagedænic Gangrene is frequently used for this disease, too. Often there seems to be a mixture of erysipelas, gangrene, mortification, and ulceration, in the same case, as exemplified thus: on a trifling-looking sore on the glans penis, for instance, the proportionably slight inflammation which is present suddenly becomes more active; the surrounding redness assumes a darker hue; then it becomes blue and gangrenous, and the parts thus affected are converted into a slough, underneath which the process of ulceration goes on so rapidly, that as the dead part becomes loose, the space behind is evidently larger than under ordinary circumstances: moreover, on the comparatively more healthy surface left after the detachment of the slough, similar actions may again speedily ensue, and thus, in the course of a very few days, according to the extent of the attack, one half of the glans or one half of the penis, or more, may be destroyed. Sometimes the patient's constitution seems but little affected; generally the pulse is rapid and full at first, but feeble as the destruction makes progress, the mouth dry, tongue foul, and indeed there are most of the symptoms of that kind of fever which usually attends severe local inflammation, particularly great prostration of strength. In hospital practice I have seen many such cases; but the patients have generally been admitted with the malady upon them; neither the air of the hospital, nor any other supposed contagious influence about such establishments, has been the cause of the disease. Occasionally, however, I have known instances where sores and wounds have assumed similar aspects spontaneously in the hospital. During several seasons in Edinburgh, thirty years ago, without any apparent cause, many sores in the hospital became affected with actions which, in some respects, resembled those of Hospital Gangrene. Healthy-looking ulcers suddenly lost their red colour, and became of an ashy hue,—the granulations having seemingly lost all vitality: then several patches sloughed, whilst ulceration extended and widened the breach of surface. I have, within the above date, seen similar results repeatedly in King's College Hospital, and have reason to think that like conditions have often occurred even in the healthiest of the London hospitals.

There are few remedies, either external or internal, which have not been made use of in these phagedænic sores, but their effects have been very equivocal. As local applications, caustics seem to have been
productive of most benefit; arsenical solutions, acetic, natrium, nitric, and carbolic acids, have all been used, mixed with water in the form of lotions, or applied undiluted to the surface: nitrate of silver, caustic potash, corrosive sublimate, even the actual cautery, have been had recourse to: again and again have they, individually been applied to the same sore, until at last the granulations have assumed a healthy aspect: during the same period many of these remedies, in appropriate doses, have been used internally; cinchona and other tonics have been given; mercury has been tried also, though it has been deemed a dangerous medicine in such cases, as being likely to encourage sloughing; change of food, change of air, and generally all such means as common prudence, combined with professional knowledge, might dictate, have been recommended and adopted;—sometimes with the apparent effect of arresting the disease; often, however, with no good result,—the sloughing and ulceration still extending, until the constitution has sunk under the continued irritation, or probably sudden death has ensued, from the opening of a large artery. In many instances, when the disease has ceased, I have often thought that time, and natural changes in the system, have produced as much good as any immediate means that may have been used; nevertheless, I should not consider any one justified in leaving such cases alone to nature: a judicious practitioner may often see opportunities of being of service, were it in no other way than cleanliness regarding the dressings, or in the exhibition of stimulants to support the sinking powers of life. I believe that there are few instances in which both constitutional and local means of treatment will not be had recourse to, and the latter must at all times be more or less in requisition. It is long since Mr. Blackadder declared the disease to be of a local nature at first; and, as in more modern times, the opinion seems to gain ground, that this and many other external affections are of a like character, the propriety of destroying the affected surface at an early period should be carefully kept in view. When the disease has seemingly changed its destructive character, and when healthy granulations cover the surface, the same kind of treatment as that required for healthy sores arising from other causes, (such as have already been described,) should be resorted to.

CHAPTER XVII.

ERYSIPelas.

It is difficult if not impossible to define between ordinary inflammation and that indicated by the familiar term of erysipelas. By common consent the word implies an inflammation of the skin—which in one instance is limited to that tissue, in another affects the subcutaneous cellular substance as well, and in rarer cases involves, less or more,
all the neighbouring textures,—showing a remarkable tendency to spread over a large extent of surface. Perhaps the latter circumstance may be deemed characteristic of the disease. The local indications of inflammation are always very distinct in this affection, the redness and swelling are conspicuous, there is great pain, and the patient often complains of burning heat in the part. The swelling is sometimes enormous, as is seen when the face and scalp are attacked. The constitutional symptoms differ little if at all from those attendant on inflammation of another sort, but there is usually great prostration in severe forms of the disease, and symptoms of a typhoid character soon appear. It is in such severe cases that shivering has been most observed as the precursor of suppuration. Sickness, vomiting, and great derangement of the biliary system are often the accompaniment of this affection, and it has been remarked that those of a "bilious temperament" are peculiarly subject to its invasions. I have retained these few last lines from former editions, but I feel bound to say that, with additional experience, and what I may call independence of thought, I feel at a loss to understand or explain in what way the "bilious temperament" is evinced, or in what it consists. The phrase sounds well; but like many others it, I fear, more characteristic of "big words" than of scientific ideas.

Like other forms of inflammation, erysipelas often commences without any apparent or appreciable cause, but it is generally observed that recent wounds and open surfaces are most liable to the disease. It may begin on a small spot and thence extend over an entire member—perhaps one half of the body; or a larger surface may at once be affected, from thence it extends still further, or here it may remain until finally exhausted. In certain cases it jumps as it were from one part to another, leaving the intermediate skin untouched. It is a treacherous, uncertain malady, and there are few inflammations in which the surgeon is more interested. Whether the disease occurs spontaneously or follows operations or accidental injuries, there may be the like need for his services.

The treatment of this disease,—should it appear in the form of erythema, with merely a blush of red on the surface,—in that of a more active inflammation of the skin, as in common erysipelas,—or in that termed phlegmonous, where suppuration in the subcutaneous cellular texture and sloughing always occur, may be conducted with advantage, according to the mode of practice which I have inculcated as applicable to the ordinary kinds of inflammation. At first the usual means to evacuate the bowels and cause moisture of the skin should be exhibited; often, more especially when the disease is spontaneous, and when the patient seems sick, an emetic will be of service, sometimes opiates may be of advantage, and it rarely happens that blue pill and opium will not be beneficial. In some instances stimulants may be deemed requisite at an early period of the disease, although they are generally of greater service in the shape of tonics and generous diet, towards the latter stages of treatment.

Constitutional treatment, in some shape or other, is invariably of service, but local measures are in most instances equally essential. I
have myself little faith in those which are said by some to check the progress of the disease in a sudden, specific, and mysterious manner,—such as the free use of nitrate of silver (a practice first inculcated and still strongly recommended by Mr. Higginbottom, of Nottingham), applied either on the inflamed surface, by way of dispelling the affection at once, or in the vicinity to check its progress, and prevent it extending further on the surface than a line marked out by the caustic; neither do I place reliance on blisters over the affected parts, nor on pressure by bandages or otherwise. It cannot be denied that erythema and simple erysipelas have disappeared under the use of such means, but it does not follow that the cure is to be attributed to them; doubtless in many instances the circumstance has been overlooked, that these conditions, so soon as they are developed, have a natural tendency to disappear, and it is probably in such cases that the marvellous effects of these measures have been evinced. Treat two cases, or any equal numbers of a similar affection, one with nitrate of silver, another with such remedies as have been recommended for inflammation, and in all probability the results will be nearly alike under either method; in one, however, there will be no pretence of suddenly arresting the progress of the disease, which must of necessity run a certain course, whilst with the other there is an affectation of power on the part of the surgeon, which, in reality, he does not possess. Similar objections may be raised to the use of flour or chalk, or smearing the part with mercurial ointment; the two former seem occasionally to have a cooling effect, and moreover they absorb the moisture, which is exuded in the form of cuticular bullæ or vesicles in many cases of erysipelas, and the latter, with most equivocal merits, has the disadvantage of being a most filthy mode of treatment. I imagine that the heating influence of flour may probably be greater than the cooling, and can see little benefit in the absorbing effect of this material, of chalk, or of any other similar remedy. When fluid is actually present, and when such means are used, a dirty cake is generally formed on the surface, which, if not soon removed, often proves a source of irritation; the secretion forming a vesicle becomes semi-purulent, and thus the supposed remedy becomes an evil. In excoriations of surface, slight inflammations from certain apparent sources of irritation, such as may be noticed in very fat children, or even grown-up persons, or from urine coming constantly in contact with the skin during any period of life, there may be no particular objection to the remedies in question, although in all such cases attention to cleanliness, and a proper change of dressings, may be equally conducive to good; but in erysipelas they are often, I imagine, worse than useless, and in the cases where they are said to have been useful it may be doubted if the disease has really been present, or if so, whether it has not got well in spite of such applications. In recent times it has been the custom with some to apply collodion in such cases, which, it is said, has acted with admirable effect. In all probability the above remarks are equally applicable here.

In erythema, which term implies the mildest form of this disease, I believe all that need, in general, be done locally is to apply warm fo-
mentations, which with the ordinary treatment for other simple kinds of inflammation, will keep the surface comfortable, until, in the course of a few days, the affection subsides. It may happen, however, that the disease will assume a more severe character, or has actually been more formidable from the commencement, but even then I would recommend the above local treatment, and, in addition, such a number of leeches to be applied, as the extent of the disease might seem to demand, or the age of the patient, and his condition otherwise, might appear to warrant. In instances requiring leeches, I should consider the disease as simple erysipelas,—that is, a more severe form of inflammation in the skin; and in some such examples, if the swelling were considerable, as it occasionally is on the head and neck, I should deem punctures with a lancet of advantage in permitting the escape of both blood and serum. I deem it right to state that, at the date of this edition, the treatment of erysipelas by leeches and punctures seems to be entirely abandoned in this country, and that my own views coincide with this change.

In the most severe forms of the disease, when from the pain and other symptoms of acute inflammation there may be every reason to apprehend the formation of matter, the surgeon should at first endeavour to mitigate the violence of the action, by the use of a greater number of leeches, if he uses them at all; if much oedema prevails, he may make a variety of punctures with the point of a lancet; and, in the event of not succeeding in this way, he should not hesitate to make one or more incisions through the skin, according to the extent of the disease, so as to give free vent to blood and serum, and also to matter, should it happen to have already formed. Possibly, however, the suppurative action may not have occurred, but, notwithstanding, the wounds will be productive of great benefit; and should the formation of pus ensue, the fluid will have ready egress through one or other of the openings.

I believe that the advantages of the practice of making incisions, so strongly advocated by Mr. Hutchinson, Mr. Guthrie, and Mr. Lawrence, have been much overrated, and that at all events the method has been shamefully abused, having been resorted to in many instances when it was not required; but, on the other hand, I am equally confident that if, in many examples, this mode of treatment had been adopted, the disease would have made less fearful ravages than have been too often observed to follow its course. Without at all wishing to detract from the modern assumption, that surgery implies much more than the "work of the hand" alone, I cannot but say, that I have seen many instances where it would have been of the greatest consequence if the practitioner had made more use of his fingers over the seat of the disease, than at the patient's wrist. I have known all the attention devoted to a supposed scientific examination of the pulse and tongue, with probably some careful inquiries about shivering, when if the fingers had once been applied over the seat of the disease, such unequivocal proof of the formation of matter would have been observed by any practical man, however inexpe-
rieneed, as might at once have dictated the proper line of treatment, and especially the necessity for giving egress to the matter already accumulated.

It is characteristic of the suppurative inflammation which occurs in the early stages of severe erysipelas, that the matter is not surrounded by an effusion of lymph, such as happens in the cellular tissue in common abscess, but, on the contrary, the fluid seems to permeate in all directions, without restraint, further than is offered by the natural firmness of individual textures, and so it may become extensively diffused under the skin, or under an aponeurosis, before it bursts through either of these textures. It is in such instances that incisions are productive of so much good. In general, division of the skin is sufficient; but where the matter lies under a fascia, the knife must be carried to the requisite depth. One, two, or more cuts from two to three inches in length, in such situations as to give most ready egress to the matter, both at the time and afterwards, should be made, and such wounds I should in general prefer to the numerous incisions of Mr. Hutchinson, the long single one advised by Mr. Lawrence, or the lancet punctures of Sir R. Dobson.

After evacuation of the matter, the treatment should be such as has already been described for abscess, granulation, and cicatrization; poultices, lotions, ointments, and bandages will all, in succession, be of service; and possibly, too, there may be sloughing both of skin and cellular substance, when the practice in regard to mortification must be kept in remembrance. In the severe forms of diffuse suppuration, the system will require powerful support from generous food and stimulating liquids. It will often happen that the stomach will nauseate such food as is usually deemed nourishing, and then possibly the chief reliance must be on soups, spirits, wines, and malt liquors.

Sometimes the disease causes such havoc in all the textures of a limb, as to render amputation the only feasible course, and this is particularly apt to occur when it comes on in compound fracture; for here, besides extensive suppuration in all the textures around, the ends of the fragments are often so denuded of periosteum, that they are certain to die.

In some, it might be said in many, instances of simple erysipelas, when, throughout the whole active progress of the inflammation, there have been no symptoms of suppuration, the presence of matter is detected when it is least expected; and this will occur, too, when the disease has, to all appearance, ceased; there may be one abscess or several, but it seldom happens that more than a few drachms or ounces of pus collect; and moreover, unlike the example of the phlegmonous form of the disease, the matter is usually circumscribed by lymph, as in the case of common abscess; indeed, I consider that for several weeks after an attack of simple erysipelas, the textures, particularly the subcutaneous cellular tissue, are extremely liable to suppuration. These abscesses should be treated according to the method already described for simple collections of matter.

There are few injuries or diseases of the body or of its textures,
regions, or members, involving the phenomena of inflammation, and its consequences, to which the foregoing observations and methods of treatment are not more or less applicable. The diseases of the skin which fall under the province of surgery, such as pimple, pustule, boil, carbuncle, and ulcers; the effects of heat, as exemplified in scalds and burns; those of cold, as chilblain and frost-bite, may all be treated according to the rules inculcated in the preceding pages; nor does it require much additional skill to apply them to those of the mucous membrane, blood-vessels, nerves, muscles, tendons, bones, sheaths, bursae, and joints. As it is not within the intended scope of this work, to name or describe the nature and treatment of all the diseases to which these textures are liable, I shall not profess to do so; but notwithstanding it will be afterwards found in treating of the injuries and diseases of the different regions, that few subjects of much interest to the surgeon, such as he may meet with in ordinary practice in this country, have been overlooked.

CHAPTER XVIII.

BOIL. CARBUNCLE. ULCERS. SCALDS AND BURNS. CHILBLAIN. FROST-BITE.

It is seldom that the surgeon's services are asked regarding a boil, but occasionally the disease is so annoying, possibly even alarming, that he may be called for. Indeed, within the last thirty years, this disease has become so much more frequent than formerly that it is very often under professional notice. A boil is familiarly known, and often referred to, as affording good illustration of the ordinary local symptoms of inflammation: there is a small tumour of the skin, a phlegmon, as it has been called, seldom bigger than a common pea, accompanied with pain, heat, and redness. Slight suppuration is almost the invariable result, and probably a small slough separates from the centre of the inflamed mass. There may be several tumours of the kind in the same locality, or scattered in other parts of the body; occasionally they are of a larger size than that indicated: they are almost always in the substance of the true skin, though in some instances they seem to involve the subcutaneous cellular tissue. Boils are most frequently met with in persons under the age of puberty, but they may be seen at all periods of life. With a single boil the constitution will be but little, if at all affected; but if there are many, there may be some slight symptomatic fever. Some individuals are particularly liable to their formation, and the hips are a frequent seat of the disease. Here they sometimes cause great vexation, as a person may be unable to sit comfortably whilst they continue.

Such an inflammation may occasionally be suppressed by pressure, by means of leather spread with adhesive plaster; but it is perhaps
best at once to encourage suppuration, as relief will thereby be most speedily obtained. The little abscess may be allowed to burst, or be opened with the point of a pin or lancet. When the matter escapes, a finely-pointed piece of lunar caustic should be pushed to the bottom of the abscess, and when the slough separates, as it will in the course of a day or two, the granulations behind will be almost ready to cicatrize. In some of these cases the patients seem of a gross and full habit of body, and a course of purgatives will usually be of great service. When there appears a predisposition to the affection, due attention should be paid to diet, air, and exercise; and in many such examples alteratives and tonics may be of essential service.

Carbuncle (Anthrax) may be described as a boil in an aggravated form; but there are sundry features peculiar to this disease. It is an inflammation of a gangrenous character, which speedily terminates in sphacelus of the affected part. Both skin and subjacent cellular tissue are involved, and a slough composed of these tissues is sure to leave a wide and deep sore. In the progress of the inflammation towards sloughing, suppuration and ulceration occur—numerous small apertures form in the skin, through which the matter exudes, or may be squeezed, and this condition of the surface forms a main characteristic of the disease; for in a boil, however large, there will be but one aperture. It is seldom that there is more than a single carbuncle at a time. The integument on the back, from the nape of the neck to the pelvis, seems most subject to the disease, but it may occur on the skin in any region. Usually it is an affection of advanced life; but it may be seen in very young persons, especially such as have been exposed to severe privations. In adults, those who have led a life of debauchery, and whose constitutions have been much debilitated thereby, are most prone to the disease. Its size may vary from that of a chestnut to that of the palm of the hand; often it is even much larger. There is never great swelling, the affected part being merely slightly elevated above the level of the adjacent skin. The flat mass is almost invariably in the form of a circle. It is in the advanced stage circumscribed by a distinct line of demarcation, which, as with other sloughs, indicates the separation between the dead and living parts. The constitutional symptoms are usually of a typhoid character, and in weak persons, advanced in life, there is great risk of sinking.

The local treatment consists chiefly in such measures as will expedite the death and separation of the affected part. Mr. French has strongly advocated subcutaneous sections as likely to arrest such evils; but in the majority of cases sloughing being almost certain to ensue, there should be no hesitation, as soon as the disease has begun to ulcerate and suppurate, about making such a division of the skin as shall take off tension and permit the closer approximation of local stimulants. A single incision, or, what is generally better, a crucial one, should be made through the skin and as much of the affected substance underneath as can be reached without touching the healthy tissues. The incised parts will speedily die after this practice, and from the first appearance of the disease, until the slough is thrown off, a poultice
should be applied. This should possess a stimulating quality, such as has already been recommended for sloughing; and when the parts have separated, a mild one (of linseed meal, perhaps,) should be continued for a few days, when ordinary dressings for healing sores may be had recourse to.

If the patient does not loathe food, a nutritious and somewhat stimulating diet should be exhibited from the first, and in many instances there will be a marked necessity for ammonia, wine, brandy, and such like means to sustain the strength. Often there will be great benefit derived from a brisk mercurial purge, followed by a saline cathartic in bitter infusion; and, towards the end of treatment, quinine with other medicinal tonics will be of marked value. Over-stimulation has occasionally done harm in some of these cases, I believe; and hence probably has arisen the practice inculcated by some of keeping the patient on milk-diet.

The term ulcer, as has already been stated in my observations upon ulceration, is generally used to denote an open sore upon any texture, organ, or region, whether the process of ulceration be present or not. The sore may be the result of such an action, or it may be a surface progressing from a recent wound towards cicatrization. There may be a loss of substance in such a sore, or there may actually be an addition, which will for a time give some increase of bulk to the part. Usually, such an increase subsides as the ulcer heals, but in certain cases it will remain more or less conspicuous ever after. If a wound is made in the skin and the edges be permitted to fall asunder, there is at first a hollow space, in shape and size proportioned to the elasticity of the skin and the extent of the wound: the hollow will, however, in the course of the healing process fill up with the lymph which will be effused; and gradually, again, this deposit or increase will disappear, until at last the cicatrix may become not broader than a simple line. Again, it is well known that when ulcers have been long in the vicinity of bone—over the tibia for example—that tissue may become thickened, and continue so throughout life, even after the ulcer is healed; and when ulcers form in bones themselves (as when caries is present) the contiguous parts often become considerably enlarged and hardened. In all instances, however, when ulceration is actually present, there is a loss of substance in the gap or open surface which constitutes the ulcer properly so called. In almost all cases a deposit of lymph surrounds (nearer the heart) the surface so affected, and the vessels, which have been partially destroyed by the destructive process, are thereby closed so as to prevent the escape of their contents. Secondary hemorrhage is a well-known and formidable result in those examples where the exudation alluded to does not happen. But most of these matters have been alluded to in former pages, and my principal object here is to point out the different kinds of ulcers usually met with, with such modes of treatment as seem most useful.

The ulcers with which the surgeon has to do are usually on the surface of the body, or, at all events, in some degree within his reach and under the influence of his methods of practice. Almost all that
form on the cutaneous surface, then, properly belong to his province,—for even those which seem to have a strictly constitutional cause or origin must be treated locally; and such as can be seen or felt on the mucous membrane, as well as those connected with articular surfaces and bones, are all subjects for his consideration.

The disease may, like inflammation, have a very apparent cause, or it may be obscure and beyond the reach of scrutiny; in one case it may be local, in another constitutional; the ulcer may be the result of a specific mechanical or chemical action, or it may arise from original defect in the system, or from some newly generated or acquired vitiating influence. In some cases the affection is of a simple character, and Nature only requires favourable circumstances to bring about a cure; while in others it is malignant, as in the different forms of cancerous ulcers, where a healing action will never take place, and it is impossible to effect a cure without a total destruction or removal of the surface and some of the adjacent parts by means of caustic or the knife.

The open sores, termed ulcers, may appear in many different aspects, and the surgeon who is most familiar with them and their nature, will be best able to treat such cases. The distinction between cutaneous ulcers, drawn by Sir Everard Home, has obtained high consideration among modern practitioners. In most instances of old standing there is usually a defect of action, occasionally an excess: in one the open surface may be almost as callous as the surrounding skin, in another the local phenomena of inflammation may all be conspicuous in a marked degree; sometimes the surface is below the surrounding level, at other times it is above it, elevated on a mound of lymph, so to speak, or possibly loose, flabby, oedematous granulations may form the open sore.

But to generalize thus, leads me from my definite purpose, which is, for the present, to refer chiefly to those sores on the legs so familiarly known under the name of ulcers. If a wound on any part of the leg be neglected, and the patient continue to move about, it is almost certain to assume the characters of a chronic sore or ulcer. The person affected may be at first so little influenced by the change as to be able to take exercise, without much inconvenience; but in the long run he must suffer from the continuance of such an unhealthy state. Possibly at a very early period the parts may be so inflamed and painful that he is obliged to take heed; but, to be brief, the surgeon may find these sores under an endless variety of aspects as to condition, shape, size, number, and locality. The part may be inflamed, tender, or callous; ulceration may be actually progressing; sloughing may be present; the surface may be composed of large, loose, flabby granulations, or it may be close upon the condition of a healthy, granulating sore. Whatever be the state, the practitioner has to see what may possibly be the cause of it, and to take his measures accordingly. In a large proportion of the cases which come under his notice there will be an evident disposition to increased inflammatory action, and if his patient can be laid up for even a few days, there will be sufficient negative proof that his former activity,
especially in the erect attitude, has been the chief cause of distress; for in a few days the acute symptoms will leave, and the sore will become covered with healthy granulations, which, if the further treatment be properly conducted, will speedily heal over. This further treatment may consist in a continuance of the horizontal position; but the healing process may be greatly hastened by giving support to the granulations by gentle pressure. It is known that a healthy granulating surface will heal of its own accord, as it were, and the process will be quick or slow according to a variety of circumstances, such as the position, distance from the heart, tightness or looseness of the skin in the vicinity, and sundry others, which need not be alluded to here; but we have daily proof that if the skin on the circumference in these cases be gently inclined towards the sore, by means of straps of adhesive plaster or bandages, the cicatrization will go on with increased rapidity. The slight pressure on the surface of the sore in such a mode of dressing has also a beneficial influence, from the support which is thereby afforded to the newly-formed and yet tender vessels in the granulations. Rest, and such a mode of practice as that alluded to, may therefore be held as the specific mode of treatment in cases of ulcers. But it is not at all times that the latter treatment can with propriety be adopted at once; indeed, there are few cases which admit of it at first sight. So it becomes one of the primary objects to bring the parts as speedily as possible into such a state; for, when once strapping and bandaging can be adopted, the difficulties are in a manner at an end. The surgeon's general knowledge of the nature and treatment of inflammation and its consequences, if it be good, will serve him greatly in such instances. His acquaintance with ulceration, suppuration, mortification, and granulation, will guide him in his treatment; not only as regards local measures, but also such constitutional resources as a knowledge of the practice of physic shall indicate.

It would be merely a recapitulation of what has already been said in former chapters were I again to allude to such topics, yet some points with reference to ulcers require special notice here. It may happen that an ulcer is in that condition when it is termed "callous." This term implies an open sore, which shows little disposition to change either for better or worse; there is little or no pain with it, there is a slight discharge of thin matter; the surface can scarcely be called a granulating one, yet it is covered with lymph of a greyish-red appearance; the edges are hard and elevated; often the veins are swollen and varicose, and, what between the indifference of the patient, and, I may add, of the surrounding parts, to the presence of the sore, as well as the callousness of the part itself, the appellation, "callous ulcer," has been well chosen. Such a surface usually requires to be stimulated. Rest, and the other modes of treatment, will not always do here; a stimulant dressing or application must be made: perhaps the resinous ointment by itself or with turpentine, will suffice; while, in other instances, a caustic or blister may be required to induce more vigorous and healthy actions. So soon as healthy granulations show themselves, support may be of value, especially if these be
varicose veins. In such instances the propriety of obliterating the veins may be taken into consideration, and I must here refer to the section on this subject in an after-part of the volume. Meanwhile I feel bound to state my conviction that in many cases of ulcers, when varicose veins are present,—"varicose ulcers," as they are sometimes called,—much benefit will accrue from the obliteration of some of the principal veins leading to or from the seat of disease. While every year gives additional proof (to my mind) of the advantage of the practice, I am equally convinced that it is almost as free from hazard as any other wound of such diminutive size. I am aware of the supposed danger of this plan, and admit that death has even been the result; I am conscious, too, that, when first applied, many deemed this doctrine rash and hasty, yet I did not adopt it without both experience and reflection, and the results have been highly satisfactory. It appears difficult to account for the efficacy of this mode of treatment: doubtless it depends upon the change in the circulation through the veins, and I imagine that the principal benefit results from the circumstance that the weight of the blood between the heart and the seat of disease is taken off, i.e., prevented from keeping the vessels near the sore in a dilated condition. It is generally understood that the horizontal position has this effect, but it may be doubted if it acts to the full extent necessary in such cases; for it must be remembered that when the veins are in a varicose condition the valves perform their functions but imperfectly; in fact, I believe that the pressure of the abdominal walls is sufficient, even in the horizontal position, to press down such a column of blood as to keep the veins still over-distended. I have watched an ulcer on the leg most carefully day by day, and seen but a slow change for the better, even though the patient was kept constantly in bed, when, having obstructed the enlarged saphena vein, a most extraordinary alteration has taken place within eight-and-forty hours, the swelling round the ulcer has rapidly disappeared, the surface itself has assumed a healthy healing aspect, and the cure has been complete in a space of time far more brief than under any other mode of treatment.

In giving support and pressure, the modern surgeon has seemingly adopted the plans of both Baynton and Whately. The former of these gentlemen recommended straps of adhesive plaster; the latter, that the part should be covered with a pad and roller. It is now usual, when the sore is considered in a favourable state for such practice (and generally that is when the granulations have risen to the level of the surrounding skin), to apply the straps first, and then the roller. The straps are put on chiefly in the immediate vicinity of the ulcer; the roller is used from the extreme point of the member upwards. The process should be effected somewhat in the following manner, supposing an ulcer on the skin:—the hair should be shaved off wherever the straps are likely to touch, then the adhesive plaster spread upon stout calico, about an inch in breadth and six or eight inches longer than the circumference of the limb, should be heated and placed with its centre on the part of the leg directly opposite the sore, when the
ends should be gently and steadily brought forward, each being made
to cross its fellow on the front, by sloping upwards, as represented in
the cut (fig. 73); then another is to be placed so as to cover about
half an inch of the upper margin of that already present, and carried
round in the same manner, and so the process is repeated until all are put
on. The lowest strap should be about an inch below the sore, the upper-
most as far above. The adhesive substance may be allowed to be
close upon the sore, or some scraped lint or common dressing may be
first laid over it. The strapping being finished, the roller must next

Fig. 73.

be applied, in the manner described in the fifth chapter on the lower
extremity, from the roots of the toes, over the foot, ankle, and leg,
until it reaches above the calf. In applying both straps and bandages,
the utmost care must be taken that no unequal pressure be kept up
on any single point, but that the support shall be the same throughout.
By such a method there is a probability of a sore mending, even
though the patient should move about on his feet,—this, indeed, being
one of the chief advantages of the plan. But it behaves both patient
and surgeon to be exceedingly cautious in taking or granting liberties
under such circumstances; for there is great risk of the limb swelling,
and of much mischief being the result. I have often seen the whole
sore thrown into a sloughing condition from an excess of zeal or hardi-
hood on such occasions.

Scalds and burns may with all propriety be brought under the
same category,—the injuries in either case being the result of heat,
which, whether it be applied in the form of water, steam, flame, or
through the medium of a solid material, will produce effects nearly
alike, each being in proportion to the amount of caloric applied. The
local effects of cold are in many respects exactly similar, and the
same may be said of chemical agents. The injury from any of these
may be such as to destroy the life of the part at once, possibly that
of the entire frame; or it may induce many of the phenomena of in-
flammation. If heat has been so intense as to induce the resem-
blance of death, the person cannot be expected to recover: the injury
to the cutaneous surface,—possibly to the air-passages,—has been
such that no constitution can bear up against it. But it is well known
that persons have been restored from a state of stupefaction resembling death, which has been caused by intense atmospheric cold. Gradual admission of heat, and removal to a warmer place, frictions, blankets, &c., and the exhibition of cordials, have been known to produce this happy change.

Scalds, burns, and the local bad effects of cold are injuries of such frequent occurrence that they are often treated by those who are not professional; and hence, probably, the variety of nostrums which are in use in such cases. It is curious to see how surgeons themselves will eagerly anticipate some peculiar effects from certain applications, and how they will change from one thing to another in hopes of discovering a specific. Yet a little reflection should serve to show the fallacy of such anticipations. If a moxa is burnt over a part so as to destroy the skin, if the heated iron be applied, or if a strong caustic be used in the treatment of disease, the practitioner never for an instant thinks that he can undo what has been done; whilst anxious to produce an eschar and discharge from the sore, he knows that it is impossible to restore the vitality of the part thus rudely treated; he knows, too, that if mortification ensues, whether it be the immediate result of injury or of inflammation, he cannot bring the part again to life. Yet he seems to have the idea that this may be done in the cases under consideration, and will even cite instances of the sort. But there is, in my opinion, a deal of fallacy on these points, and I doubt not that many cases of supposed cure have been examples where the local injury has been of the most trifling kind.

Scalds and burns may be of many different sorts; the surface may be merely a little over-heated, the injury may be such as to induce vesication, and possibly subsequent inflammation, of which the effects may vary from the simplest to the most severe, or the parts implicated may at once be deprived of vitality. In the simplest of these examples the surgeon should know that time alone will bring about a favourable change; and in the more severe forms he may see that he has to cope with inflammation and its consequences. Like other injuries, burns when of a severe kind are almost invariably followed by such a state of shock and general collapse, that there is constant risk of the patient sinking; indeed, in such instances, the surgeon’s care is so much required constitutionally, that it forms the principal feature of his practice. The seeming amount of pain must not be taken as a criterion of the severity of the injury, for usually in a simple scald or scorch, it is greater than when the tissues have been suddenly deprived of life. The apparent amount of injury, joined with the state of shock, will best enable the surgeon to judge of the character of the injury.

When the shock is severe, stimulants in the shape of ammonia, wine, brandy, and others of like nature require to be plentifully administered, and opiates will always be of service in allaying the pain. Locally, the appliances which have been recommended are almost beyond number. In the simpler forms of scalds and burns, cold
appears to possess advantages over all others; it allays pain, arrests inflammation, and, if applied in good time, may obviate vesication. Should the case be more severe, still it cannot do harm, excepting that it is unfavourable to the condition of collapse; it is therefore necessary to be cautious in applying it, especially when the injury involves a portion of the trunk. I have known instances where persons have fallen into vats of boiling fluid, who on being picked out have been immediately immersed in cold water; such cases are manifestly beyond remedy; but in examples of a less formidable sort, a similar practice has proved all that could be desired. Sir George Ballingall has related, in his work on Military Surgery, a very interesting case of this kind. A person had his back scalded with boiling water, from the nape of the neck to the pelvis, and was, on the spur of the moment, induced to set himself down in a running stream which was close by. His cries of agony were speedily changed to notes of pleasure, and being kept in the water for a considerable part of the day, he arose with "little or no perceptible mark of the injury." Cold may be applied in a great variety of ways, and most of these having already been alluded to in the chapter on inflammation, I need not again enumerate them. Doubtless the "specific" characters of many remedies are attributable to this agent,—the solutions of various salts, the subacetate of lead for example, and vinegar—the noted nostrum of Mr. Cleghorn, probably owe their chief virtues to it. But vinegar, if applied undiluted, may have a stimulating effect, and some have imagined that remedies of this class are all-powerful. The ancient doctrine, "similia similibus curantur," has at all times been held good by many parties, but certainly it is well to use it according to modern homoeopathic customs. Turpentine is the most famous of the stimulants that have been used in these cases, and was much extolled by Dr. Kentish of Newcastle: but its specific virtues admit of great doubt, and probably the good effects from it are chiefly the result of the constitutional reaction which the local irritant induces. Perhaps the most recent agent is a solution of carbolic acid as used by Professor Pirrie and others, and doubtless it may be tried like its predecessors with similar éclat, until superseded by the next fashion.

In many instances local stimulants are highly useful, just as they are in cases of sloughing; and vinegar, turpentine, resinous tinctures, and such like, are of service in severe examples. In all such cases the parts are generally least painful when excluded from the air, and light unctional applications are most agreeable to the patient's feelings. Lard, olive-oil, or simple cerate will each be useful, and one of the most noted remedies in modern times is the combination of lime-water and linseed oil (linimentum calcis) in equal parts. This application has been long in use among the workmen engaged in the extensive Carron Ironworks in Scotland, and I know of none better. The chief objections to it are the nauseous smell, and its aptness to soil the bed-clothes. The latter may be in some degree avoided by means of oiled silk, or Macintosh cloth; and a less offensive mixture may be made with olive-oil instead of the other. The liniment in question
answers for burns in all stages and conditions; but when there are sloughs, a linseed-meal poultice is, perhaps, the best application which can be used. Occasionally some stimulating fluid may be combined with it so as to hasten the separation of the dead portions of skin.

In simple vesication there may be little need for any attention excepting to take care of the tender part, and to leave the cuticle, which has been raised by the effused serum, still upon the surface until a new portion is formed. Occasionally a great mistake is committed by those who see these cases in an early stage, in removing the cuticle. The excitement is invariably increased by such a proceeding, and suppuration will probably be the result. Vesicles may be punctured to permit the serum to escape, and perhaps this will be best with larger ones; but often if small they may be let alone, and evaporation will take place through the upraised cuticle. In more severe forms of injury, where possibly the cuticle, perhaps even a thin film of skin, has actually been destroyed by the heat, the case must be treated as a wound that is certain to suppurate and slough, and the same local mode of treatment is requisite in examples where the parts have been more deeply destroyed. After separation of the sloughs the surface must be treated as a granulating sore, and the further progress, as regards the healing process, will be in proportion to the loss of skin,—for if this has been great, the cicatrix forms very slowly. In such instances the surgeon has to watch the healing process narrowly, to counteract as much as possible any deformity that may threaten; yet often, with all his care, this cannot be avoided. More, however, will be said on this subject in other parts of the volume. American surgeons have greatly extolled the efficacy of cotton in cases of burns, and it is occasionally used in this country when it happens to be at hand. The injured part may be enveloped in it, and should be uncovered according to the indications. I cannot imagine that it possesses any "specific" virtues, unless as a soft covering which excludes the air and prevents unnecessary interference and further injury from over-officiousness of those in attendance. If there be sloughing, the practice must be abandoned.

The danger of these cases may be considered as bearing a just proportion to the extent of parts destroyed; but some patients are in greater hazard from shock than others. In severe cases there is always greatest risk within the first few days; but, as with other violent changes effected on the system, some internal viscus may become the seat of secondary inflammation, and death from a secondary cause may be the result. Mr. Curling has the merit of having represented that in some of these cases, the upper part of the small intestine (duodenum) has been found in a state of ulceration on its mucous surface within a few weeks after such primary injuries.

Occasionally local injuries from heat are so extensive that it becomes necessary to remove the part entirely by amputation, which may be primary, intermediate, or secondary, as the surgeon shall deem best. I have seen amputation at the shoulder joint performed on three several occasions for severe burns of the upper extremity.
The mildest form of mischief from cold where the surgeon's advice is asked for, is chilblain, which may be said to be a sluggish kind of inflammation induced partly by cold and partly by heat; perhaps in reality the condition is more the result of the latter than the former, for, if the change from cold to heat were less abrupt than it usually is in examples of the kind, there would probably be no such affection. Chilblain is only seen during the most inclement season of the year, when the toes and fingers, perhaps the ears and tip of the nose, are liable to be chilled out of doors, and suddenly heated again in the house, especially if the part be brought near a fire. The disease shows itself as a small dusky-red, elevated spot, which is most conspicuous while the person is warm. At this time, too, there is a painful tingling sensation, which induces a desire to rub and scratch the affected part. There may be one chilblain only, or there may be many; and sometimes the hands and feet are covered with them, when they cause great annoyance. In some instances slight vesication appears, and at other times, if the feet be much exposed, ulceration and sloughing may ensue. In mild cases, where the skin is unbroken, a stimulating lotion is perhaps the best application which can be used. The camphor or ammonia liniment, or these in their compound shape, may give relief; one or other of them may be used in conjunction with soap liniment, or the latter may serve by itself, or with a small portion of turpentine, or tincture of cantharides. Many nostrums have been used for these complaints, and occasionally they seem to be of use; but I am doubtful if any application possesses such virtue as to lead to a confident hope of cure from its use. If the temperature of the air becomes mild, the affection ceases spontaneously, and perhaps it is at this particular time that the remedy in use acquires its good character. If ulceration or sloughing be present, poultices and stimulating dressings must be used until the sore assumes a healing aspect, when simple dressings will complete the cure.

If the temperature of a part be much and long depressed, there is great danger of its concurrent death; and should the heat be too speedily restored, there is equal danger from reaction,—an excess, as it were, of that milder excitement which induces chilblain simply. The inflammation under these circumstances speedily assumes a gangrenous character, mortification ensues, and the part must separate as a slough, or be amputated by the surgeon. Portions of the feet are frequently lost in this way, and a sketch of such a condition will be found on a future page, as an example where Chopart's incisions for partial amputation may be adopted with advantage, in preference to an operation higher up. If sloughing of the whole thickness of a part takes place, the surgeon had better apply his instruments than leave the disjunction to Nature. I have often seen amputation required in such cases at a future date. In this country it is rare to see such severe effects from cold, yet cases occur from time to time; and it has fallen to my lot to be engaged with a considerable number. I have twice seen amputation done in both legs at the same time, and in one instance performed Chopart's operation on both feet. One of
the two cases alluded to occurred in the Infirmary of the Wandsworth and Clapham Union, and was operated on by my friend, Dr. Connor, of Battersea. The patient, a female, aged 17, had suffered great privations ere she was taken to the establishment named, and though well nigh exhausted by her previous distress, and also from the extensive mortification, which involved the greater part of each foot, made an excellent recovery.

CHAPTER XIX.
DISLOCATIONS, FRACTURES, FALSE JOINTS.

So much will be afterwards said on these subjects, especially dislocations and fractures, when each individual kind is referred to, that few general observations are here required regarding them.

The term dislocation, or luxation, is used to indicate the separation of articular surfaces from each other either by accident or disease. The latter cause is rare in comparison with the former,—at all events, when it does happen it by no means forms the most important feature of the case;—it is not the displacement which the surgeon has to deal with so much as the disease of which it is one of the features.

The observations on dislocations in this chapter have reference entirely to such as are the result of external violence. The separation of the articular surfaces thus produced may be partial or complete. In the one instance the cartilages may not be entirely severed, while in the other they may not be in contact at all. Luxations at the knee and hip afford good examples of these two kinds, for the articular surfaces of the knee-joint are so extensive, that it rarely happens that the tibia is completely parted from the femur, whereas in the hip-joint, the articular cartilages are invariably thrown out of contact, and thus the luxation is what is conventionally termed complete. The practical value of such a distinction is, that the lesser degree of separation implies a proportionally small amount of injury.

The slightest displacements of articular ends of bones cannot possibly occur without stretching, and probably lacerations of some of the tissues connected with them, and where the separation is very palpable the synovial capsule must be more or less torn open. However great the separation be, so long as the parts are not exposed to the external air the luxation is called a simple one,—in contradistinction to the instance where there is some wound in the skin communicating with the injured parts, when it is called compound. The former of these implies a less serious wound than the latter. Occasionally, besides the damage to the parts composing the articulation, some neighbouring tissue or organ is injured at the same time, when the case is termed complicated; and should it happen that this complication involves a very important part—perhaps the main artery of the limb—the
amount of injury may be estimated more on account of this particular feature than as being a luxation.

Terms of the above kind, and of similar import, have been used in cases of fractures. A partial fracture, however, is of rare occurrence, as it generally happens that the break implicates the whole thickness of a bone. The fissure may run in almost every direction—longitudinal, oblique, or transverse; the latter being the most common, the longitudinal the most rare, while in many instances there is a combination of the two latter, or of all three. There may be one fracture in a bone, or several, and sometimes it is broken into many portions, the fracture being then termed comminuted.

The causes and symptoms of these injuries will be specially referred to afterwards. Neither can be produced without considerable, if not great violence. There may be a predisposition to either, from the shape or laxity of a joint, or from fragility of bone; but violence is required to induce them. This may be external influence, as heavy weights falling on the person, or the weight of the body falling on a joint or particular member, or possibly the violence may come from over-action of the muscles connected with the part. But all such causes can be readily appreciated by one conversant with anatomy; and the same may be said regarding the symptoms. I should be sorry that any professional person should be content to look in this page alone for information on such points; yet, for the sake of regularity, and for beginners in surgery, I shall here take some brief notice of the general symptoms of these injuries.

In luxation there will be more or less distortion, and the articular end of one of the bones may probably be felt in its unusual position, while a deficiency may be detected in the natural site; the limb may be lengthened or shortened—generally the latter is the case; at first there will be considerable freedom of movement; but within a few hours the muscles will become more than usually rigid, and it will be impossible at any time, unless the disunion of tissues be very great, to put the limb through all its usual movements. In the rigid condition the axis of the limb is unnatural and not in accordance with that of the member on the other side. In very fat individuals it may be difficult even at first to detect distortion of the joint itself; and in all cases where the swelling resulting from the injury is developed, the difficulty is still further increased.

In fracture the bending permitted in the part is the most conspicuous symptom in most instances; but there are many cases where this feature is not remarkably distinct. Distortion may, or may not, be apparent. If there is much displacement of the portions (or fragments, as they are called) of the bone, there is almost invariably shortening of the limb; but the flat and also the round bones are liable to fracture as well as the long ones, and shortening need not be looked for in them. The grating of the fractured surfaces against each other, technically called "crepitus," is usually deemed the surest symptom of the nature of the accident: it is often difficult to detect, however, when the symptoms otherwise are tolerably distinct. Inability to use the
limb is a good criterion, too, in the generality of cases, but in both luxations and fractures persons have been known to use the injured members in the most remarkable manner. Sir Astley Cooper has referred to examples where persons have walked a considerable distance on the end of the tibia in compound luxations of the ankle-joint; and there are few surgeons of experience who have not known instances of men having made considerable use of members after the principal bones have been broken. A case which came under my care will be referred to afterwards, that of a man who worked the greater part of a day in the reaping-field after a severe fracture of the clavicle; and I have seen a person stand upon the injured limb when the femur was broken without impaction below the trochanters.

A simple dislocation may be looked upon as a severe contused and lacerated wound, which, however (the parts not being exposed to the air), has all the tendency to heal kindly; but if the dislocation be compound, if, in other words, the injured joint be exposed to the air, then high inflammation is likely to result, which is almost certain to end in suppuration. That this does not always occur is fully proved, by the occasional successful results of compound dislocation of such joints as the knee and shoulder, and even when suppuration ensues, there is ample proof that there may be a possibility of saving both life and limb, as is sometimes exemplified in compound luxations of the ankle.

In luxation it should be remembered, that so long as the displaced end of the bone is allowed to remain in its unnatural situation, it acts in some degree as a foreign body, and therefore the sooner it is replaced the better. But this is not the chief and only reason for an early interference. If inflammation has already begun, the patient suffers much more than he would do if reduction was set about at once; and, moreover, in consequence of the swollen condition of the soft parts, there must be greater difficulty in accomplishing the proceeding. There are few surgeons who would not at once attempt reduction, and I should scarcely here refer to the subject, were it not that I believe there are some who incline to delay. Doubtless, after the lapse of time, and after the use of leeches and fomentations, or perhaps cold lotions, the inflammatory swelling which follows a dislocation will in a great measure subside; but assuredly each day which passes with the joint in its distorted condition, only adds to the pain and difficulty afterwards. In all instances then, unless there be some good reason to the contrary, I recommend an early attempt at reduction. If this be accomplished, one great cause of inflammation will be removed; and it seldom happens that there is any occasion for alarm at the slight inflammatory action, which must, of necessity, result from an injury of this kind. The practice of anaesthesis in modern times gives additional reasons for carrying out these precepts.

The constitutional means which may be adopted to facilitate reduction, and the most distant period of time at which it should be considered advisable to attempt the proceeding, will be noticed in reference to the shoulder and hip, and proper occasion will be taken to point out
DISLOCATIONS, FRACTURES, FALSE JOINTS.

127

how extension and counter-extension are to be applied, whether by the hands alone, or by the aid of different kinds of apparatus. It is right to state here, however, that anaesthesia has in a manner superseded all other means for producing muscular relaxation, and facilitating reduction without pain.

The above remarks are almost equally applicable to fractures. Whether such injuries be simple or compound, each must be deemed a lacerated and contused wound, to be followed by considerable, if not severe, inflammation. So long as the fragments are not strictly in apposition, the greater will be the amount of local irritation. It is, I believe, a common practice with some, to wait until the inflammatory swelling has in a great measure subsided, ere any attempt is made to set the fragments in their proper place. Others, at an early period, put the fragments and the whole limb in the position in which it is intended that they shall lie during the cure, but make no attempt to fix the parts by means of splints, pads, and bandages, until inflammation and swelling have, in some degree, gone off. I believe that the latter plan is absolutely necessary in certain instances, and that the former may occasionally be deemed advisable; but, as a general rule, I feel satisfied that it is best not only to set, as is the technical term, the fracture, but to apply such apparatus as may be deemed requisite, as soon after the surgeon sees the case as circumstances will permit.

The admirable practical remarks of Mr. Pott, and of Sir James Earle, on this subject, seem to be overlooked by practitioners of the present day, but the advantages of an early re-adjustment are so apparent, that it is scarcely necessary to quote such high authorities to enforce the practice.

The smallest deviation of the fragments from their natural position must be productive of greater irritation than when the broken surfaces are accurately opposed, and therefore, with few exceptions, they should be so placed at the earliest possible date. I have no doubt that if all fractures were set within an hour of their occurrence, the subsequent inflammation and swelling would be less severe than they usually are; but the surgeon who is to be responsible for a case, may not see it for some days after the accident, and it is in such instances, perhaps, that there may be doubt as to the propriety of immediate adjustment. In fracture of the patella, for example, as will be afterwards stated more particularly, the fragments are usually separated from each other by the fluid which collects in the joint, and it is not until absorption takes place, that approximation can with propriety be accomplished. In the upper third of the thigh, too, the swelling from effused blood and inflammation is occasionally so great, that attempts to extend the limb are productive of little or no benefit. In such examples, however, by proper attention, the fragments may be at last placed in excellent position. But even here, I imagine that the correct rule is to reduce and adjust as speedily as possible, and at whatever time a bandage is applied in such cases, it may be considered a general rule that its application arrests further swelling.

In dislocation, as soon as reduction is accomplished, the need for the
surgeon has almost ceased,—the act of reduction seems the chief part of his duty; and moreover, it may be said that, in general, it is the only occasion on which any active interference on his part is required. Not so, however, in fractures: the proper adjustment of the fragments only, as it were, begins the treatment, and for weeks after, the surgeon has to give careful attention to their position, and to see that the bandages, splints, and other apparatus are properly applied. It often happens that after the first dressing there is no further occasion for the surgeon's interference; but he acts unwisely who gives a case no further notice until the time comes for taking off the coverings; for, besides the frequent necessity for loosening or tightening the bandages, averting undue pressure on particular points, ascertaining that no unusual inflammation is going on, no vesication on the surface, no suppuration within, it is incumbent on him, also, to observe that no displacement occurs during the movements of the patient, or otherwise, so that in such an event he may take the earliest opportunity of putting the parts right again.

I am convinced that success in the treatment of fractures depends much more on these attentions, than on any marked superiority in particular forms and kinds of splints and bandages. Out of the many cases treated in our public hospitals, there are few examples met with of marked deformity; yet it is doubtful if the apparatus used in such cases is altogether alike in any two establishments; and the results are often equally good in the instance when no splint or bandage is made use of, as when the most complicated instruments are had recourse to. These results then, in my opinion, are chiefly to be attributed to the skill and care of the surgeon,—skill in the original setting and adjustment, and care in the after management.

With few exceptions it will rarely be necessary to use leeches, or other such means, to subdue the inflammation which follows simple fracture;—rest and good position being chiefly to be relied on. When great injury has been inflicted, it may be well to use some precautions lest the inflammation should run on to suppuration. Leeches and fomentations may possibly be deemed advisable; but, in general, cloths wetted with cold water, or a cooling lotion, may be preferred. If suppuration ensues, the matter should be evacuated at an early period, for if it is not already in contact with one or both fragments, it may speedily be so, and caries or necrosis may be the result.

In compound fractures, the treatment must be varied according to circumstances. At first, the fragments must be set as in the case of simple fracture, with the exception that the wound on the surface must not be covered in a permanent manner,—the splints and bandages being so placed as to permit the application of any dressings that may be deemed necessary. If the wound in the skin is slight, an attempt may be made to effect union by the first intention, and if this succeeds, the case must afterwards be treated exactly in the same manner as a simple fracture. If, however, the wound suppurates, which is likely enough in a considerable proportion of cases, the application of poultices and water dressings, as in the treatment of suppuration under
other circumstances, must be resorted to; and when the matter does not appear to have free egress, more convenient openings should be made. The diffusion or infiltration of pus, which often occurs in such cases, is thereby rendered less likely, and a few incisions at first (that is, when suppuration has occurred, or when the inflammation is high—perhaps of a gangrenous character), judiciously made, may probably avert the necessity for amputation, which is in modern surgery happily only the occasional result of compound fracture. In cases where the discharge of pus is very profuse, it is difficult to keep the bed-clothes so clean as might be desired; neither is it possible to prevent offensive odour. Dr. J. R. Barton is in the habit of surrounding the limb, in such examples, with dry bran, and the plan has been strongly advocated by Dr. Norris, as being serviceable during the extremely hot weather of an American summer. Solutions of chlorine and of per-manganate of potash are much used in such cases to obviate the disagreeable emanations, and wood or peat charcoal may be used for the same purpose with great advantage. Within these few years, the use of carbolic acid, in solution or in paste, has been much extolled by Professor Lister, for cases of compound fracture, both as a deodorizer, and as having special virtues in preventing or limiting the formation of pus. Hence has arisen the extensive use of carbolic acid in all wounds generally when suppuration may be anticipated, and there are many practitioners who seem to be convinced that it has extraordinary powers in arresting suppuration. It is beyond doubt that thousands of wounds have united without suppuration when this agent has been employed; but the same may be said of instances where it has not been used, and suppuration has often occurred when carbolic acid dressings have been faithfully applied. Whatever course of practice may be necessary for inflammation and its consequences, the strictest care should be taken to keep the fragments in good position, and perfectly quiet, and the means of doing so will be best explained in describing the nature and treatment of individual injuries of this sort.

The question of amputation in compound fracture is frequently one of great interest, and it will be canvassed in other parts of this work. In all instances when a limb is injured beyond the hope of recovery, there seems little doubt among the present race of surgeons, that immediate or primary amputation should be performed. The chief difficulty seems to consist in determining which are the cases where attempts may reasonably be made to save both limb and life, and whether in saving the former such a useful member will be preserved as to warrant the risk to which the latter may be subjected. In all instances of doubt I should lean to that decision which might save mutilation, whenever it appeared that the future circumstances of the patient afforded a fair chance of recovery; but assuredly I should neither consider it a matter of gratulation, nor an illustration of judicious practice, that the surgeon had refused to amputate, for the sake of preserving a limb, which at best could only be deemed an eyesore and an incumbrance. It will be afterwards found in these pages, that I am no advocate for interference by means of operation when other
measures may suffice, especially when that interference implies the loss of an important member; for in my opinion as much good judgment may be displayed by patiently watching the efforts of nature, as by an officious meddling; but, on the other hand, I cannot admire nor sanction that kind of surgery which inculcates the saving of a limb at all hazards, merely for the sake of avoiding amputation; hazards, too, which involve the life of the patient, and the probability of an ultimate necessity for this operation.

More than fifty years ago a method of treating fractures without splints was recommended by M. Sauter, of Constance, and Dr. Mayor, of Lausanne, and a mode of swinging broken bones was also recommended; but while both plans are occasionally followed in the present day, and although I think highly of the practice of suspending fractures of the leg, I cannot sanction the treatment without splints. The objections to this practice seem to me so apparent, that I wonder how such a mode could ever have had its advocates. There is no deficiency of evidence that fragments will unite without the aid of splints, nor is there proof wanting to show that occasionally they will not unite, however carefully any kind of apparatus is applied; but in my opinion it cannot be doubted for an instant, that a broken limb is in a much safer condition when properly put up in splints than when left altogether unprotected. I must refer, however, to my remarks on the treatment of fracture of the leg for further illustrations on these subjects.

It may be observed that, in my notices of fractures of different bones, no particular allusions will be made to separation of the epiphyses—diastasis, as the accident is called—a kind of injury which is occasionally met with in the young subject; and the reason for this is, that I know of no difference of treatment which such cases may require, whilst every anatomist must be aware that a solution of continuity is as likely to occur in such situations as elsewhere. If they deserve especial comment, it is that crepitus will probably be less distinct, and also with reference to the proximity of the injury to a joint; but on the latter point, the principles of treatment for ordinary fractures are equally applicable, whilst if the symptoms are so obscure as to make crepitus essential to the diagnosis, it is evident that if there be a fracture at all, it must certainly be one of a comparatively simple character.

Whatever care be taken with fractures, it will sometimes happen that the fragments do not unite by means of bone. In such cases there is either a total absence of that vascular action which produces callus, or whatever amount of it there may be, there is no disposition towards union and consolidation of the parts which have been separated. Under such circumstances a false joint is said to have formed.

Occasionally there is a very evident cause for non-union, whilst in some instances the utmost skill cannot divine any other than that which is the usual resource of our ignorance—viz., a peculiarity of constitution. I have seen an instance where the chief cause of non-union seemed to be the constant interference of the surgeon, who, in his anxiety to afford all the skill in his power, used to take down the splints, and put them up again every second or third day, so that the
DISLOCATIONS, FRACTURES, FALSE JOINTS.

parts really had not that rest which is of such essential service in the early stage of treatment. I hope it will not be supposed that this is the kind of attention which has been recommended in a preceding page; for when once all the parts and apparatus are properly adjusted, there should be no further interference, unless there be an absolute necessity.

In examples where the cause can be ascertained, the surgeon may not have the remedy in his power, or at all events he can but wait, in hopes of a more favourable action coming on, as in the case of a compound fracture where necrosis has ensued, when he must allow time for the separation of the dead portion. In one constitution, consolidation will take place much more rapidly than in another; but we cannot calculate with certainty on the period that may be required for this event, either on the score of constitution or age, excepting in the latter case, when fracture occurs under puberty or in early infancy, for then we know that the formation of callus goes on more rapidly than at any other period of life. I have treated several examples of fracture which had taken place during birth, and have remarked how speedily the fragments have become firm. I have seen several instances to the contrary, however, where false joint in the leg was formed in early life, which, in one example, at first caused lameness and deformity, and ultimately, as the patient's weight increased, necessitated amputation.

In false joints, as in most other abnormal conditions resulting from injury or disease, with which the surgeon has to do, it is well to ascertain in how far constitutional remedies may be of service. A case, remarkably illustrative of this observation, once occurred to me in the Royal Infirmary of Edinburgh. A man, about fifty years of age, came under my care for a simple transverse fracture in the middle of the thigh, and, after the lapse of three weeks, when all swelling from effused blood had gone off, and the muscles and other soft parts had diminished considerably in size, the ends of the fragments could be felt rubbing against each other, as if the surfaces had already become, in some measure, smooth. From the flaccid state of the muscles, and apparent deficiency of vascular action, there was reason to dread the result, especially as the patient seemed to fall off in health daily. Nutritive food had no good effect, and I was at a loss what to do. Although assured by the patient that he had been temperate, from his looks there was reason to suspect the reverse, and he was ordered a reasonable quantity of whisky during the day. The change seemed marvellous! within a week, his countenance brightened up wonderfully from its previous sickly and languid aspect, swelling took place around the seat of fracture, and in little more than a month from the time that the use of the spirit was first commenced, a most excellent cure was accomplished. Had this most common-place mode of treatment not been resorted to, I verily believe that this person would have died, and that, too, without the smallest reparative local action.

In certain parts of the body, and under certain circumstances, a false joint is almost sure to be the result of fracture, and is in some
DISLOCATIONS, FRACTURES, FALSE JOINTS.

degree desirable, as, for instance, in fracture of the neck of the thigh-
bone, where it is seldom expected that bony union will ensue; more-
over, such a result in this situation, and in advanced years, when the
accident occurs most frequently, is as good as need be desired; but
there are few other parts of the extremities where false joint is attended
with so little trouble and inconvenience. A case has been referred to
by the late Mr. Marshall, where a recruit passed the ordinary exami-
nation as to his physical condition, who had a false joint in the fore-
arm. I have myself seen instances where a similar state caused but
little inconvenience; but, in general, if the fragments remain disunited
in the leg, thigh, or upper arm, there must be such a loss of power as
to induce the patient to submit to any reasonable proceeding on the
part of the surgeon, to bring about consolidation.

The subject of false joints, whether resulting from fractures or dis-
locations, will be frequently referred to in future pages, where parti-
cular cases will be noticed; meantime it may here be stated, that in
the treatment of non-union, it would be well to resort to almost any
reasonable measure before cutting down to the parts, as was done by
White. After the lapse of six, eight, or ten weeks, friction of the
ends of the fragments against each other, gentle, or active, according
to circumstances, should be had recourse to, and after exciting
increased action in this way, the parts should again be kept quiet for
ten or twenty days, as in the first stage of the treatment. If this do
not suffice, then the patient should be allowed or desired to move about
a little, with instructions, if the fracture is in the arm or fore-arm, to
use the limb as he may feel inclined, and if in the lower extremity,
permission to rest upon the part at will. Here, perhaps, the starched
bandage might be resorted to; and should success be still wanting, a
blister or a seton might next be tried. I have, on many occasions,
seen this last method resorted to, and have remarked the difficulty of
passing the thread between the fragments, as was originally done by
Dr. Physick: but I do not consider it absolutely necessary that it
should be between them, as I believe it may answer equally well when
in proximity, for the desired inflammation may be produced in this
way with as much certainty, perhaps, and often with greater safety,
than when the thread is carried through the fissure. In the leg or
fore-arm, it may not be very easy to avoid important vessels or nerves.
The thread must be passed with an instrument of a length proportioned
to the thickness of the limb, and if the common seton needl be used,
it must be remembered that its sharp sides may possibly cut what
should be avoided. I have seen the radial artery wounded in this way.
If a probe is preferred, and used in the manner already described for
passing an ordinary issue seton, the bistoury, which must be in requi-
sition in such a proceeding, may do harm. I have seen the surgeon,
unable, or unwilling from judicious caution, to pass a needle or probe
between the disunited fragments of the tibia, leave the latter instrument
sticking for many days in the fissure, and the proceeding was attended
with all the benefit that could have been expected from the cord, had
it been carried between the fragments.
DISLOCATIONS, FRACTURES, FALSE JOINTS.

133

I would cut down to the fragments only as a last resource, and, on doing so, be regulated by circumstances, whether the exposed surfaces should merely be scraped with a knife, or actually cut away with the saw. In the leg or fore-arm, I should resort to the latter plan with great reluctance, especially if only one bone was at fault. I have known an instance where, in consequence of a portion of the tibia having been removed at the period of reducing a compound fracture, no new bone was produced, and the fibula afterwards proving insufficient to support the weight of the patient’s body, amputation was ultimately performed. The best part for resection is in the arm, and it would only be the most urgent necessity that would make me attempt such an operation in the thigh. There is a preparation in the museum at King’s College, exhibiting an instance where such a proceeding might have been of the most essential service: a loose portion of bone is seen lying crosswise between the two chief fragments, so as to keep them from coming into contact. Here, if an incision had been made, the fragment might have been very readily removed, and, doubtless, with a successful result.

It must be kept in view, that when resection is performed, the fracture is converted into a compound one, and the hazard is, therefore, considerable, particularly in the thigh, where this species of fracture is so very dangerous.

Even at best, the treatment by resection cannot be deemed a certain mode of cure. Besides the risk of limb or life which attends this practice, there is a possibility that, after all, union will not take place. In my own practice I have been disappointed in this way, both in the humerus and femur. In one example, in the upper extremity, in a boy about nine years old, the ends of the fragments had become very attenuated, and when resection was effected, they were still disproportionately small. There is, indeed, still so much doubt as to the result of any known treatment for the cure of false joints, that the surgeon gives ready attention to any new proposal, which shall hold out a prospect of a satisfactory result in these cases. The late Professor Miller, of Edinburgh, proposed that a variety of incisions should be made in and around the false joints by means of a narrow blade, such as is used for subcutaneous section of tendons. This instrument may be carried freely among the deep parts, and yet the wound in the skin may be so small, that neither danger nor trouble need be apprehended from it. One puncture or several may be made at convenient points, and besides division of soft parts, the ends of the fragments may be scratched and scraped, so as to induce action there also. The object of these wounds is to produce such excitement as may lead to the formation of callus, and so bring about the desired bony union. Mr. Miller adduced several examples of success with this procedure, and it seems to me well worthy of trial, especially before resection is undertaken. I have tried it repeatedly, but without success. I believe, however, that in these instances a favourable result would not have followed any method, and in two of them the plan by resection, afterwards tried, failed also. Dieffenbach proposed to expose the
end of one or both fragments by incision, and then bore holes in the bone, into which pins of ivory should be introduced and left for some weeks, until the required excitement should be produced. This practice has seldom been resorted to in this country. Mr. Stanley adopted it in St. Bartholomew's Hospital, and the success was complete in the instance referred to. I have also myself been very successful: but the same plan has not proved satisfactory in the hands of Mr. Square, of Plymouth, who tried it years ago in the Devon and East Cornwall Hospital. Any other foreign material, of an equally bland character, would act as well as ivory, I presume, and the case above alluded to, where a silver probe was left between the fragments, may be deemed analogous. Other surgeons have tried the practice above referred to. Among them I may mention Mr. Hey, of York, Mr. Teale, of Leeds, and my former colleague, Mr. Bowman, under whose care a most interesting case of the kind occurred in King's College during the summer of 1851, some of the particulars of which will be found in the section of this volume on the lower extremity.

In 1864, Mr. Bickersteth, of Liverpool, laid before the Medical and Chirurgical Society of London a proposal to cut upon the ends of the bones, and clip or saw them in a slanting direction, so as to make a splice, which was secured by iron pegs passed through holes drilled in the bones (Trans. Med. Chir. Society, vol. xlvii.), and the practice in his hands and those of others seems to have been very successful. In my early days I often heard of the proposal to cut upon the broken surface, and tie them together by means of wires passed through holes bored on the occasion; but few, if any, authentic cases were made known. In recent times, since wire has been so freely introduced into surgical practice, owing chiefly to the zealous recommendation of Mr. Marion Sims, wires have been freely applied in these cases; and I have much satisfaction in recording that my own personal experience, which has been considerable, particularly in most unpromising cases, has been highly satisfactory. I have succeeded in this way in the arm, forearm, and leg, when most other plans, even cutting on the fragments, had failed; and cases of the kind will be referred to afterwards. The main object of the operation has been to cut freely upon the fragments, to make their ends raw with the forceps or saw, and to tie the surfaces together, however roughly, with the hope that severe inflammation would afterwards set in. This has generally happened, and after the lapse of six weeks or three months the wires have been cut upon and extracted.

Mr. Jordan, of Manchester, has drawn especial attention to the importance of reserving the periosteum in all instances of cutting operations in these cases; and I most cordially agree with him on the subject.
CHAPTER XX.

DISEASES OF BLOOD-VESSELS. ANEURISM.

Many of the diseases of blood-vessels, especially those of the arteries, are of more interest to the pure pathologist than to the practitioner in surgery. They are such as cannot be readily recognised on the living body, and even when the surgeon suspects or recognises their presence, he has no control over them. Here I may allude to the chronic thickening of tunics, and the steatomatous and atheromatous deposits which are so familiar to the pathologist. I might even include the calcareous or ossific deposits which are so common, I may almost say constant, in the arteries of old people; but such a condition is more frequently recognised in the living body than those above referred to.

The tissue of blood-vessels is liable, like all others, to inflammation, and most of the usual results follow. Adhesion, suppuration, ulceration and sloughing, happen; but these conditions require no special comments here. Perhaps the most interesting fact that we learn from a knowledge of the morbid changes to which arteries are liable is, that with defective elasticity there is a tendency to rupture of tunics and the development of aneurism in one or other of its forms. Those aneurisms which are the result of wounds, must be excepted from this observation, and so also must that particular kind which is known as aneurism by anastomosis. The last-named disease will be specially considered in the chapter which follows this one, and the various operations for aneurism most commonly in use, will be carefully described in future pages; but the disease requires some separate and general notice at my present progress.

A knowledge of inflammation and its various effects will lead to a just appreciation of such conditions in the veins, and so much is said elsewhere regarding injuries of these vessels, that I shall not dwell upon such subjects here. I must refer to other parts of the volume for some observations upon the admission of air into the veins, and for the consideration of that dilated condition to which the term varicose veins has been applied. The sections on the Head and Neck, and on the lower extremity, will supply the chief information which I deem worthy of place in this work upon these subjects.

The symptoms of aneurism are generally so distinct, that there is seldom any difficulty in detecting the disease. A tumour, in the course of a large artery, pulsating synchronously with that vessel, diminishing in size, when the blood is prevented from passing into it, by pressure either upon it or upon the vessel nearer the heart, and accompanied by a peculiar sound, usually now-a-days termed "bruit de soufflet," which is recognised by applying the ear directly over the swelling, or through the medium of the stethoscope, can scarcely be
mistaken for any other disease. But some of these symptoms are occasionally indistinct, and others not altogether to be relied upon: thus tumour or swelling may depend on other affections, and pulsa-
tory motion may be very indistinct, from the presence of fibrin, or it
may be communicated by a contiguous artery. The "bruit" above
referred to is not esteemed by Mr. Porter and other recent authorities
as altogether infallible, and I have myself examined instances when it
did not serve to clear up existing doubts. The sound, indeed, may be
produced in almost any large artery by pressing the stethoscope over
it and applying the ear. I have seen a most experienced and judicious
surgeon cut through the parietes of the abdomen, with the intention
of tying the external iliac artery, for a supposed aneurismal tumour,
situated immediately above Poupart's ligament, which, however, in the
progress of the operation, turned out to be a malignant affection of the
lymphatic glands; and have known the same excellent practitioner,
for a tumour which baffled the diagnostic skill of many seniors around
him, place a ligature on the main artery, under the supposition that
the disease was aneurism, when it was ultimately proved that he was
correct. Mr. Liston opened an abscess in the neck, as he supposed,
which was thercupon discovered to be an aneurism; and Mr. Syme,
in The Edinburgh Monthly Journal of Medical Science, has re-
corded an instance in which he placed a ligature on the common
carotid, for a supposed aneurism, at the upper part of the neck, which,
on the subsequent death of the patient, proved to be an abscess. Such
instances of doubtful character, or of mistaken diagnosis, it must be
admitted, are rare; but fortunately for the surgeon, it is seldom that
the symptoms are very obscure, although on all occasions it behoves
him to be cautious in his diagnosis. To mistake another disease for
aneurism is assuredly a serious matter; but not so bad as the con-
verse. Most surgeons of experience must have met with cases of
aneurism at the root of the neck, wherein some ignorant non-pro-
fessional parties have been advising the use of poultices, and ultimately
of the lancet. I have myself known many instances of the kind, in
which, happily, however, the latter advice had not been complied
with.

Many of the usual pathological distinctions between different kinds
of aneurism seem to me of little value practically. Thus, it matters
not to the surgeon whether a poplitical aneurism be true, false, or
mixed. If the disease arises spontaneously, which here it almost in-
vvariably does, I know of no difference in practice more applicable to
one case than another, provided always that circumstances are favour-
able otherwise for an operation. The most experienced cannot tell
when an aneurismal sac is formed by dilatation of all the tunics, so
as to constitute a "true aneurism," or merely condensed cellular
texture, such as constitutes "false aneurism;" nor can he be sure in
what instances there has first been expansion of all those tunics, and
then a rupture of the two internal, with further distension of the ex-
ternal, as is the definition of a "mixed aneurism." If, however, the
aneurismal swelling be the immediate result of a wound, he may then
be sure that it must be circumscribed solely by the surrounding cellular texture, the term circumscribed or diffused being applicable chiefly in accordance with the palpable meaning of these two words. Unless the malady be the result of a wound, or of ulceration (a case of extreme rarity), it is impossible to form a correct idea of the state of the tunics, excepting with reference to the age of the individual; and, therefore, however interesting these points may be to the pathologist who examines such tumours after their removal, or after death, I repeat that the supposed condition of the tunics of an artery in spontaneous aneurism ought not in any way to influence the practice of the surgeon, in so far as selecting an operation for its cure is concerned, provided always that there is no evidence of arterial disease elsewhere.

The distinctions between aneurism in one vessel,—common aneurism, as it may be called, and that dilatation of numerous small vessels which constitutes aneurism by anastomosis, are, however, sufficiently important to demand separate consideration, and the latter disease will be particularly referred to in the next chapter. Meantime, I wish it understood that my present remarks are intended for that form of tumour which is connected with a single large artery.

The operation which Anel performed,—tying the humeral artery for the cure of aneurism at the bend of the elbow, has often been quoted to show that Hunter was not original in placing a ligature on the main artery leading to the disease, at a point nearer the heart; but the grand difference between the cases in which the operations were performed by these surgeons, does not seem to have been appreciated, or at all events, clearly pointed out, by all who have discussed the question of priority. Hunter operated in a case of spontaneous aneurism, Anel in one where the vessel had been wounded. In the former case there was every reason to suppose that the vascular texture was not in a state of health, as evinced by the spontaneous dilatation or bursting of the artery; in the latter, the puncture with the lancet had evidently occasioned the disease, and there was no reason to deem the vessel, immediately above and below the wound, otherwise than healthy. Anel did his operation in an instance where most of our best authorities would still perform the old operation. Hunter tied the femoral artery at a distance from the poplitical aneurism, to avoid the acknowledged disadvantages and dangers of the operations previously performed in similar cases. In punctures of the humeral artery during venesection, there is sufficient evidence to prove, that if ligatures be placed above and below the seat of injury, the vessel will close permanently; and before Hunter's operation, there was no lack of testimony as to the formidable results of all preceding operations.

But such questions do not require to be argued at the present day; and I may, therefore, proceed to state generally, that in spontaneous aneurism, when it occurs in any part of the body, where it properly comes under the care of a surgeon, and when an operation for its cure is resolved upon, the ligature is usually applied at some considerable
distance from the diseasc; on the other hand, if it is the result of injury, delegation may be resorted to, as close to the orifice in the vessel as may be found convenient. Thus, in the humeral artery, when injured during venesection, a ligature is applied immediately above the wound, and to prevent bleeding from the lower orifice, which may take place in consequence of free anastomosis, another is applied immediately below: the aneurism is actually cut into, and the blood or fibrin turned out. In spontaneous aneurism, however, when a ligature is applied, the tumour is untouched,—left entirely to nature.

The practice in these different cases will be more fully illustrated afterwards, and it should be here observed that there may be exceptions to some of these general rules. As, for example, in an aneurism of the femoral artery resulting from a wound, the surgeon would act more wisely in placing a ligature upon the vessel at a point nearer the heart, and leaving the tumour untouched, than by cutting down to the seat of injury. Here the recurrent circulation is not so much to be dreaded as in the arm, and there is every probability of the cure going on as it would in a case of spontaneous disease. I wish it to be remembered that the practice here recommended has reference to aneurism, and not to a wound of the vessel, with the blood flowing from the surface, for in such a case I might, perhaps, prefer exposing the vessel at the seat of injury.

As it is not my present object to detail all that has been done or may be done in the treatment of surgical disease, I need here only state, that, for external aneurism, the only certain remedies which the surgeon possesses, are pressure upon or ligature of the vessel, with which the disease is connected. Pressure has in modern times proved wonderfully successful, and in all eligible situations there need be no hesitation in giving it a trial, although it would be wrong to be invariably sanguine as to the favourable issue. It may be applied over the tumour, on the artery leading to the diseace, or partly on both, as will be afterwards particularly explained. I know of no other remedy on which the smallest reliance should be placed: the different proposals of causing coagulation, or deposits of fibrin, by means of cold, passing threads through the tumour, or heated wires into it, by electricity, and by other methods, are all, in my opinion, of the most feeble and generally futile character; and the trials that have been made of them on the living body, should be considered valuable, chiefly on account of the assurance which they have given, that their success has not been such as to encourage repetition. Success, in a single instance, with one or other of such plans, may possibly occur; but I should deem it unjustifiable, in most examples, to tamper either with the disease or the patient's credulity, in persisting in their use, or in many instances even applying them at all.

In internal aneurisms which are beyond the reach of surgical art, there is, of course, every propriety in resorting to a trial of one or all of those methods which have been proposed for the purpose of encouraging a spontaneous cure. Such practice as recommended in former times, by Valsalva and others, and often called the medical
treatment, is rarely if ever passed over in a treatise on aneurism. It may be said to have consisted essentially in a kind of starving process, while the patient was brought almost to death’s door by venesection and deprivation of food. Only such diet as might be supposed to keep soul and body together was permitted. After more than forty years’ experience, I must confess that I have never seen an instance where this method has been of avail. I have often seen it tried, but have not even met with a person who could steadily follow the instructions, and generally in hospital practice the patients have declared that they would rather die of the disease than of starvation, with which they seemed to be threatened. In most of the cases where this practice is supposed to have been successful, I am of opinion that other causes have been at work. It has fallen to my lot to watch a number of cases where all the symptoms of aneurism have spontaneously disappeared. I have seen an instance of what seemed an undoubted aneurism of the aorta, projecting on the right of the sternum, gradually and spontaneously disappear, whilst the patient followed his occupation of a house-painter. I can give no cause for this happy result. It certainly was not from treatment. I prefer the modern Dublin doctrine, that theoretically more is to be expected from keeping the blood thick (full of fibrin) than by rendering it watery, in accordance with the old theory; but in reality, so far as regards a cure, I have no confidence in either view. But as it is not my purpose to speak particularly of what is usually termed the medical treatment, I need not refer to it further than to add the testimony of my own experience to the amount of evidence already obtained, that, however laudable it may be to resort to such, we possess no internal remedy which seems to have the smallest specific influence on the disease; at all events, such an influence as to lead to a certain cure.

Since this chapter was first written, the method of treating external aneurism has undergone a great and important modification. Pressure has again been had recourse to, and with such admirable results as to arrest the attention of all practical surgeons. Dr. Hutton, of the Richmond Hospital, Dublin, treated a case of popliteal aneurism successfully in this way in November, 1842, and soon after, the practice was followed with the like happy results by Drs. Cusack, Bellingham, Harrison, and other surgeons. Mr. Liston succeeded in the same way with two examples of femoral aneurism, and Dr. Bellingham was also fortunate with a case of the kind. The last named gentleman published a valuable paper on the subject in The Dublin Journal of Medical Science for May, 1845, and enumerated twelve instances of successful practice by means of pressure, nine of these having been aneurism in the popliteal artery, and three in the femoral. Such results are very different from those obtained by Guattani in former times, for, out of fourteen cases related by him where pressure was had recourse to, only seven of them succeeded, and the method was probably less favourable in the hands of others. In popliteal aneurism it was Guattani’s custom to compress the tumour and also the femoral artery as high as the groin. The pressure applied in the cases cited
by Dr. Bellingham has been on the main artery alone, and therein the practice differs considerably from that alluded to; but even this plan is known to have failed with Hunter, Sir Wm. Blizard, and many besides, although from time to time examples of success occurred, as with Richerand, Dubois, Dr. Todd of Dublin, and others. But the kind of pressure now employed is less severe than formerly, when it was deemed requisite to keep the surfaces of an artery so forcibly together as not only to prevent the circulation in it, but to induce inflammation, adhesion, and consequent obliteration of the canal. This amount of pressure (in the groin for example), was generally beyond the patient's endurance, and the practice was often abandoned on that account; but the plan now proposed is such as to obviate this disadvantage, for it is founded on the knowledge that complete obstruction of the main current of blood towards an aneurismal tumour is not essential to the cure. If the current be merely impeded and diminished in calibre, the desired changes in the disease and in the collateral vessels may go on as satisfactorily as if a ligature were around the artery. Dr. Bellingham points out, in the paper referred to, that "in the histories of the cases which have been published, the femoral artery could be traced after the cure to near the sac of the aneurism; proving that the artery is never obliterated at the point compressed." The pressure, therefore, need not be such as to cause great distress, and it may be shifted from place to place by using two or three tourniquets, or, as has been suggested by Mr. Weiss, by having several screw-pads on the same instrument, the force from each being regulated by the feelings of the patient. The Irish surgeons (who, in my opinion, deserve the greatest credit for having so judiciously revived this practice) seem, according to Dr. Bellingham's account, to give preference to an instrument which "consists of an arc of steel covered with leather, at one extremity of which is an oblong padded splint, the other terminates in a nut, containing a screw, to which a pad similar to that of the tourniquet is attached." I doubt not that the ingenuity of surgeons will readily devise appropriate apparatus for each case that reasonably admits of this mode of treatment; and as we have the proof that a slight comparative pressure is what is chiefly required, I imagine that it would be well to give this practice a fair trial before resorting to the uncertain and hazardous proceeding with the knife. If pressure be judiciously applied, there cannot be the smallest amount of additional danger to the patient, while no one can answer for the result when the Hunterian operation is performed. Should the pressure not suffice, the last resource may still be adopted, with as much prospect of advantage as at the beginning. But it is perhaps too early to argue such matters until there is further proof as to the wisdom of the practice; meanwhile, there is, in my opinion, ample encouragement to proceed in the course already so happily begun by so many of the leading men of the day. I shall allude to this subject in after parts of the volume.

Since these remarks were published in a former edition of this work, the treatment of aneurism by compression has attracted further atten-
tion, and the results, in the hands of Irish surgeons especially, have placed the success of the practice beyond doubt. Much credit is due to Dr. Bellingham of Dublin for the attention he has paid to this interesting subject, and Mr. Tufnell, of the same city, is not less worthy of praise. The latter gentleman has published a most admirable treatise upon it, and Dr. Bellingham's most recent views have been published in a short paper on the Treatment of Popliteal Aneurism by Compression, in the thirty-fourth volume of the Transactions of the Royal Medical and Chirurgical Society, 1851. From this paper it appears that 36 cases of external aneurism had been treated in this manner in Dublin, during the preceding seven years. To use Dr. Bellingham's own words, "in 29 of these a cure was effected by compression; of the remaining seven cases the artery was tied in 2, the patients recovering. In 1, pressure was discontinued, the aneurism subsequently diminished in size, and the patient had the perfect use of the limb for three years, when symptoms of aneurism of the aorta supervened and compelled him to give up his employment. In 2, the limb was amputated, the patients recovering; and in the remaining 2, death occurred, in one from pulmonary disease, in the other from a severe attack of erysipelas; but, in both, the local disease was very nearly cured, the aneurismal sac being almost completely filled by fibrin deposited in concentric layers." In not one of these cases can it be said that evil resulted from pressure. If erysipelas was the result of the interference of the surgeon, it was more likely the sequence of the galvano-puncture, which was resorted to in this instance in conjunction with compression, than from the pressure. These 36 cases were treated by 21 different surgeons, and both numbers give fair practical inference of what may be expected from a continuance of the practice among surgeons generally. The method has been tried frequently by others than the Dublin surgeons, but as yet we have no data from their cases to form any positive conclusions regarding it. Many instances have been mentioned to me wherein it has failed, but I have heard of many more in which it has been successful; and if Dr. Bellingham's Table—which, as we learn from the Dublin Medical Press, for December 3, 1851, has since been increased to 62 cases—be contrasted with some of those, showing the results of ligature of the superficial femoral artery in the hands of various surgeons, the balance seems greatly in favour of compression. It has been ascertained by Dr. Norris, that of 188 cases, in which the operation was performed, 46 died, the majority of this number being from causes directly attributable to the use of the knife. In 6 of the cases of recovery in the above list, amputation of the limb was required. Of 119 cases of popliteal aneurism collected in a tabular form by Dr. Crisp, 16 died, and in 6 of those wherein recovery took place, amputation was resorted to. So far as our comparatively limited experience in the method by pressure, as followed by the Dublin surgeons, will enable us to form an estimate of its value, it seems in many respects, if not in all, preferable to that by deligation of the main artery; and there seems these great advantages in it, that if it does not act satisfactorily, the Hunterian operation may still be resorted to,
with as much probability of success as ever, while by its application none of those formidable dangers are incurred, which are the well-known consequences of the application of the ligature. The difficulties and immediate dangers of a cutting operation are avoided. It may seem strange to make use of such language in the present day, as applicable to ligature of the superficial femoral artery—for that, I assume, to be the vessel meant by the unfortunately vague term of "femoral;" nevertheless, when it is known that great difficulties have been experienced in such a proceeding, even by hospital surgeons and teachers of surgery, and that the accompanying great vein has been wounded by different operators, the facts cannot be overlooked. Mr. Syme states in the Edinburgh Monthly Journal of Medical Science for Nov. 1851, that he has tied the superficial femoral artery twenty times without a fatal issue, and with perfect success, and both he and his patients may be congratulated on such satisfactory results; but the Tables above referred to show no such average success: and when it is borne in mind that the attempt at cure by pressure does not preclude the resource of the ligature, it seems to me that, with the ample evidence before us of the great success which has attended the modern practice by this means, the surgeon should undoubtedly give it trial, ere he resorts to the knife. Unquestionably the evil result of the Hunterian operation, in regard to ligature of the superficial femoral artery, has in many instances resulted from the defective or injurious style of operation, but the same may be said of certain examples where pressure has failed. Granting both of these statements to be correct, it cannot be overlooked that ligature of the superficial femoral artery, done to the perfection of human skill, has nevertheless been followed with the worst possible results. I have seen Mr. Syme perform the operation repeatedly with admirable skill and precision in all points, and the results have been all that could be desired; but I have seen many others, and among them I may name Mr. Liston, perform the same operation, with an equal amount of tact and judgment, yet the results have been very different. With pressure, surgery has still further resources, but with the ligature the fate of the case is, for a time, placed almost, if not quite, beyond human power; and doubtless the surgeons of Dublin who have resorted to this practice (many of whom stand among the highest of those who have graced the annals of the profession) have duly considered all these points.

I must refer to the chapter on ligature of the vessels of the inferior extremity for some further notice of this important matter, and for a description of the instruments for applying pressure in this locality.

In the practice of surgery, the application of a ligature to the vessel with which the disease is connected, has a powerful and specific effect; and although the operation for its accomplishment is not without danger, both at the time and subsequently, it possesses such advantages over all other modes of practice (pressure excepted in eligible cases), that the surgeon who, when other circumstances are favourable, hesitates to adopt or recommend it, may with justice have either his skill or his sincerity called in question.
ANEURISM.

The immediate effect of a ligature is to check the flow of blood through the disease, either entirely or to such an extent as shall, by impeding the influence of the heart's action, permit the contents of the sac to consolidate. In aneurisms at certain parts of the body, it cannot be doubted that after the main vessel has been obstructed by operation, circulation still goes on, though with diminished force and quantity. Sometimes this is quite appreciable; as, for example, in the popliteal artery, where pulsation often can be felt after obstruction of the femoral; the same has occurred, too, in an inguinal aneurism after ligature of the external iliac; at other times the surgeon cannot feel pulsation, although a very considerable current of blood may be passing along, as is proved by what sometimes happens after ligature of the subclavian artery for wounds and aneurisms of the axillary. A case will be referred to afterwards where such an operation failed,—bleeding continued; a similar case has lately been described in The Lancet,—the collateral vessels keep up the hemorrhage; and, indeed, in my opinion, complete obstruction through the main vessel, at the seat of injury or disease, does not occur in all instances of such operations, and is not absolutely necessary for the cure of aneurism. It was on such views that Mr. Wardrop proposed his operation of impeding the circulation through the subclavian artery, or through the carotid in aneurism of the innominata, by placing a ligature on the vessel on the distal side of the tumour, being a modification of the original proposal of Brasdor, who imagined that obstructing the vessel beyond the disease might have the desired effect.

The operations of Brasdor and of Wardrop are resorted to only in cases where all other modes of treatment are unavailable, especially when Hunter's cannot be put into practice, such as in aneurism at the root of the neck. All experience goes to show that the proposal by the two first-named authorities can be undertaken only as a last resource, and one, also, on which no great reliance can be placed; whereas Hunter's operation may be resorted to with every probability of success: but here it must be remembered that no one would recommend the former when the latter is applicable;—in other words, the instance where Hunter's operation is practicable, is not altogether so desperate, as when either of the others alone holds out a ray of hope. It may be said that Brasdor's and Wardrop's operation, the latter in particular, has been more successful in aneurism at the root of the neck than Hunter's;—ligature of the innominata for aneurism beyond having only once succeeded, whilst deligation of the subclavian for aneurism of the innominata has actually, in several instances, been followed with every good result that could be anticipated. But more will be said on these interesting subjects when I come to the head and neck; meantime I shall limit my observations to Hunter's operation.

The usual circumstances which induce the surgeon to hasten an operation of any kind whatsoever, or to wait a more favourable opportunity, will always influence him in selecting a proper period for such a momentous one as ligature of a main artery. I do not apply such a
ANEURISM.

high-sounding term to the mere manual proceeding, for that is of
minor consideration in comparison with the effects which may be pro-
duced on the patient: a pupil from the dissecting-rooms may place a
ligature on the femoral, subclavian, or other large vessel, with as
much precision as the most experienced operator, but the most skilful
surgeon cannot foretell what may be the result; and it is in this
light that the proceeding must be deemed momentous. Experience
has taught that it is wrong to wait, after an operation has been deter-
mined upon, in the hope that by allowing time for the collateral
vessels to enlarge, there will thus be less chance of mortification occur-
ing immediately afterwards. This doctrine formerly prevailed with
reference to the popliteal and axillary aneurisms, and the tumours
were occasionally allowed to attain an immense size; now, however, it
is the practice to operate in such cases at an early date, mortification
being rarely dreaded, and being moreover as likely to happen in the
one instance as the other, perhaps most so when the tumour has at-
tained a great size. Instances, however, are not wanting to prove,
that when the swelling is very small there is no immediate hurry; I
have myself watched one, of undoubted character, on the axillary
artery, for several years, and could observe no perceptible increase in
its size; and examples where spontaneous eures have occurred within
a certain period might also be adduced to sanction the advice against
precipitancy. I have seen a case of popliteal aneurism, where all the
symptoms were distinct, and where an operation was contemplated
within a brief period, in which, before the time agreed upon had
arrived, all pulsation in the tumour had ceased, and the disease under-
grew a spontaneous cure. But I believe the general rule of operation
at an early period to be a good one, and would not delay, when such a
proceeding was deemed necessary, excepting for some other and better
reasons than those above referred to.

Two aneurisms, one in the ham and the other in the groin, on the
same limb, have been cured by one operation on the external iliac
artery; and the disease has been successfully treated by the Hunterian
operation, first in one limb and then in the other, as occurred in the
practice of Sir W. Newbigging. In such cases I deem it almost as
unnecessary to inform the young surgeon that he may operate, as to
remind him of the impropriety of tampering with an external disease,
whilst there is an incurable internal affection present. It may be well,
however, to keep this circumstance in view, that when aneurism has
come on spontaneously in one part of the body, it may possibly have
done so in another; and therefore in all external cases of this disease,
a strict investigation should be made as to the condition of the large
internal vessels. I need not here allude to all the circumstances that
may have influence for or against an operation, but I cannot help re-
ferring to one case which has come under my notice. Mr. Watson, my
former colleague in the Royal Infirmary of Edinburgh, had a case of
popliteal aneurism in a female six months gone with child; an opera-
tion was determined on, but circumstances occurred to prevent it. In
the mean time the late Professor Hamilton’s opinion was taken as to
the propriety of operating on a female in this condition, and he advised against it. The patient returned to the country, and in due time was delivered. In the interval the disease had greatly increased in size; in childbed the limb became additionally swollen, the limits of the tumour became less distinct, and death, from puerperal fever, occurring ten days afterwards, afforded Mr. Watson an opportunity of ascertaining by dissection, that the aneurism had suppurated and burst into the knee-joint during the course of the fever. Although the advice for delay under the peculiar circumstances came from such a high obstetrical authority, and admitting, as I do, that all formidable operations should, if possible, be avoided at such periods, I think it may fairly be doubted whether in this case it would not have been better to have operated at the earliest date at which the patient sought advice. Were a similar case to occur to me, I should feel inclined to proceed at once, although it must be admitted that many circumstances might lead a judicious surgeon to delay.

The individual operations for aneurism will be particularly described afterwards: but, to save frequent repetition, I may here state, that the incisions through the integuments over a large artery should always, if there is no reason to the contrary, be very free; and that those in the vicinity of the vessel should be limited, and so cautiously made as to disturb it in the smallest possible degree. The old practice of carrying the finger under an artery, is now out of date, and the same may be said of that of passing a couple of threads or more around the vessel at different points;—a precaution which was, erroneously, supposed to guard against secondary hemorrhage. Among surgeons of the present day, the general custom seems to be that of only exposing such an extent of the vessel, as to make sure of its identity, and to permit the introduction around it, of such a needle as that delineated at p. 34, and such a ligature as that described at p. 29. The treatment of the wound must be conducted according to the ordinary principles of surgery, and the most probable after-events will be specially referred to, when each individual operation is under consideration.

The same kind of practice, with reference to the ligature, which I have inculcated in previous pages, should be adhered to in the operation for aneurism. The thread should be drawn sufficiently tight to prevent it from slipping from its place on the artery, or the knot from loosening. In tying a ligature in this operation, as well as in amputations and other large wounds, I imagine that, if these two objects be kept in view, it signifies little about the particular effects on the arterial tunics, or whether the two innermost be divided or not. I believe it will scarcely be possible to sink the noose sufficiently deep in the artery, without dividing the inner and middle coats, and am also of opinion that the adhesive inflammation is much more certain after such an injury than when the tunics have been merely laid in apposition: but it cannot be doubted that adhesion and obliteration will occur under either circumstance, and the nicest perception in him who draws the noose will not, on all occasions, indicate the exact amount of laceration of these tunics.

L
The proposal of using temporary ligatures, by allowing the thread to remain on the vessel any period from a few hours up to fifty or more and then removing it, although successful in the practice of Travers, Roberts, and others, seems to possess no decided advantage, whilst there are strong and obvious reasons against it; and the same may be said of gut, wire, and other materials not referred to previously, which have been proposed as ligatures, either temporary or until ulceration should cause their separation.

The practice with regard to aneurismal varix and varicose aneurism, may be partly ascertained from observations in some preceding pages, but will be more particularly referred to in the surgery of the upper extremity.

CHAPTER XXI.

ANEURISM by Anastomosis.

Aneurism by anastomosis is, in most respects, so essentially different from other kinds of aneurism, as to require some separate notice, especially in this part of my work, as it is a disease which may occur in any region of the body, and the general principles of treatment are, under ordinary circumstances, alike applicable to all.

The disease may be characterized as a growth of a red or bluish colour, beginning usually in a small spot, and increasing, rapidly in one case, slowly in another, until it becomes prominent and conspicuous, forming a soft tumour, which almost entirely disappears under pressure, but speedily attains its accustomed size when let alone. It is most frequently seen in the skin and subcutaneous cellular texture, especially about the scalp, face, and neck; but it may be observed in any region, deep-seated or superficial, affecting only a portion of the limb or the whole textures. A finger or toe may be the seat of the disease, and it is not unusual to see the entire thickness of the lip affected. The streaks or coloured outlines (enlarged vessels) on the surface betoken its vascularity: if the tumour be of some considerable size a "bruit" may possibly be heard on applying the ear; a thrill, perhaps even pulsation, may be felt by the fingers. Heat, exercise, vascular excitement, will render all the symptoms more distinct than under ordinary circumstances, and in infants they become very perceptible during crying or any unusual muscular effort. Some tumours of this kind are much more vascular than others, and it is in these that the symptoms are best marked. Occasionally the vessels run in so thick a mass of condensed cellular tissue, and the skin over is so natural in appearance, that the true character of the disease is apt to be overlooked, and may possibly be discovered only when the surgeon interferes with the knife. A most instructive and interesting case of this description has been detailed by Mr. Liston, in the twenty-sixth volume of The Medico-Chirurgical Transactions: A boy, ten years old, had a
tumour in the popliteal space, of an oval shape, three inches and a half in length, with the skin over it in a natural condition, and, at the time, having none of the symptoms of an erectile disease. The mass had "a doughy, elastic feel, when the limb was extended, a sensation much resembling the fluctuation that is produced by deeply-scated matter. When the limb was flexed this sensation was less distinct, and the tumour had more the feel of an elastic solid mass, which was pretty moveable, and might be distinctly raised and separated from the bone." Mr. Liston proceeded to remove this tumour, under the supposition that it was of a fatty nature, and only discovered its real character as he proceeded. A case somewhat analogous occurred to myself during the summer of 1843: A lad, nineteen years of age, came into King's College Hospital for the purpose of having a tumour about the size of a duck's egg removed from his cheek, and after, as I thought, a careful examination of the mass, an operation was proceeded with under the impression that it was a cyst. I was, however, greatly astonished to find that it was supplied with numerous large vessels; that it had in point of vascularity many of the characteristics of this formidable disease, and was fain to apply ligatures as speedily as possible, with the double object of arresting the bleeding and causing the tumour to slough away. The details were published in the second volume of The Lancet for 1842-43.

Some of the peculiar characters of this kind of aneurism were first clearly pointed out by John Bell, whose descriptions of it are as sensational as any that ever came from his pen. He imagined that it consisted of enlarged arteries and veins, communicating freely by cells of the cellular tissue; but most pathologists of the present day agree, that what he considered cells, are merely dilated and tortuous vessels, inoculating directly with each other, and my own investigations lead me to acquiesce in the latter view. Many years since, I had occasion to amputate the foot for a large aneurism by anastomosis: on injecting it afterwards, the fluid (rather a coarse one) passed readily from the arteries into the veins, by direct continuity, and the dissection, which was made by my assistant at the time, Mr. Stephen Stanley, subsequently of the Royal Navy, and one of the companions of the gallant Franklin, showed several large channels of communication. The preparation is in the Museum at King's College.

Mr. Bell, in his descriptions, makes allusion to the resemblance which the disease has to erectile tissues, such as the penis in animals and the gills of the turkey-cock. He gave it the name of Aneurism by Anastomosis; but recently, from the example of Dupuytren and others, it has often been called the Morbid Erectile Tissue. The terms nævus, and subcutaneous nævus, have often been used of late years, too, but I fear with some degree of confusion. I know of little or no physical difference between the disease described by Mr. Bell and that spoken of by Mr. Wardrop, under the name of subcutaneous nævus, but between the latter and the nævus maternus there are important distinctions, and it is a pity, I think, that these two terms should have been confounded, and applied, as they often are, to one and the same
disease: the mother's mark being, in reality, only a red or bluish appearance, occasioned by a peculiar arrangement, perhaps even enlargement, of the vessels of the skin, showing no tendency to increase, and being in no wise dangerous, or even troublesome; whilst the subcutaneous naevus has all the symptoms, properties, and dangers of the disease originally described by Mr. Bell, under the title of Aneurism by Anastomosis.

An unusual form of vascular enlargement is occasionally met with in the finger or hand, which has not, in so far as I know, been particularly described by authors. There is great distension of the vessels, especially the veins, which are so filled and expanded with blood as to give the surface a dark colour. The condition resembles what is usually termed aneurismal varix more than the true aneurism by anastomosis; but there are many more vessels enlarged than in the last-named condition. Perhaps the term varicose aneurism would be more appropriate here than it actually is to the condition to which it is applied; and I may on this subject refer the reader to my remarks on the different kinds of aneurism which may be met with at the bend of the elbow. Some years ago we had an example of the condition to which I allude, in one of the patients at King's College Hospital, on whom several of the fingers and a portion of the hand were affected, and the accompanying cut (fig. 74) is from a cast of this case. I have since seen in Dr. Thibert's collection of models, the cast of a most extraordinary instance of the kind, involving almost the whole of the upper extremity as high as the shoulder.

In some of these instances the superficial veins are chiefly affected, and, in others, while the parts near the surface seem perfectly sound, the deep-seated veins are principally involved. I had a remarkable instance of this latter kind under my care in King's College Hospital. A lad, nineteen years of age, had a large vascular tumour on the heel, which occasionally burst on the surface, and bled so profusely as to endanger life. In the course of treatment amputation was required, and it was found that the tibial veins were enormously distended, although the cutaneous veins in the leg were in a healthy and natural condition.

It is rare to see this disease commence after infancy; we often see it in early life and in the adult, but in most instances we find that it had been first noticed soon after birth. In general, we cannot appre-
ciate the cause, but in some cases it can be distinctly traced to a blow or contusion. I have seen it in various localities from such causes.

The disease is rarely accompanied with pain. Sometimes it seriously impedes the functions of a part, but usually the cause of distress is either from its appearance on some conspicuous part, or from its gradual increase and corresponding threatening aspect. In certain cases it ceases to grow after a time, and even (though such examples are rare) will undergo a change for the better; it may, in fact, undergo a spontaneous cure, by gradual diminution in the size of the vessels, or by a sudden process of sloughing.

If such tumours are so situated that they do not produce either inconvenience or annoyance, and if they display no tendency to increase, they need not be meddled with. Slender hopes should be held, however, of a spontaneous cure. In certain localities, as on the face for example, it is generally advisable to interfere at an early date, and the disease may be treated by local measures, or by a mode similar to the Hunterian operation. In the first of these methods, the object is either to alter the condition by exciting inflammation, or to remove the tumour by excision, or by taking measures to induce sloughing; in the second, the force of the current of blood being taken off, diminution of the swelling succeeds, coagulation perhaps occurs, adhesion, and obliteration.

In certain instances, local treatment cannot be adopted, as when the disease occurs in the orbit, antrum, or other deep-seated parts; and, in such cases, ligation of the common carotid, or other large vessel, whose branches lead directly to the disease, is the only resource. Fortunately, such operations have often proved successful, and so there is some encouragement to adopt them, although I should on most occasions, when practicable, be inclined to prefer local measures only.

If it is not wished to make free use of the knife, a variety of plans are at the command of the surgeon, with which he may attempt a cure—the immediate object of all of them being inflammation. This process may be excited by vaccination, by caustic, by heated wires, by pressure, scions, single threads, by subcutaneous incisions, or by injections of irritating fluids among the vessels forming the disease.

The method by vaccination is rarely put into practice; for, although the disease is often congenital, it is seldom that any operation is thought of, or required, before or at the usual age for this proceeding; moreover, it is only in instances where the tumour is very small that such a mode could have sufficient effect. It is, however, a plan well worth consideration in such cases as demand interference at such an early period of life, and although it often fails, I have known examples wherein it seems to have answered.

Caustic potash has been used with good effect; but unless the tumour be diminutive, and the agent freely applied at first, or often repeated, it is, in my opinion, inferior to some other modes of treatment. Strong nitric acid may be used with great effect, and I prefer it to most other caustics, although many others of a similar kind may be used.

Pushing heated wires or needles into such tumours, will cause sloughing and inflammation.
Pressure may be in some cases applied, both on the tumour and on the vessels leading to it, as on the scalp, for instance; but it can seldom be done with great effect. On children, who are most frequently the subjects of practice for this disease, it is difficult to keep bandages and hard pads properly applied, and it does not often happen that the tumours are so situated that the plan can be available. Unless there be bone immediately below the mass, sufficient pressure cannot be applied. This method has first the effect of preventing the blood from circulating in the enlarged vessels, and then producing inflammatory action. Of pressure by means of plaster of Paris I have neither experience nor faith.

I have frequently obliterated small vascular points by passing a needle through the disease, and turning a thread around it as in making the twisted suture. If the tumour be considerable, two or more needles may be used, or two may be crossed in the manner represented in the cut illustrative of the treatment of varicose veins in the leg, and the thread may be turned in all directions, so as to keep up equal and efficient pressure on every part of the disease. In such cases a band of lint twisted round the needles will prevent the threads from causing ulceration. On these occasions, I have sometimes withdrawn the needles in the course of eight-and-forty hours, in other instances, allowed them to remain longer—probably eight or twelve days, and in some to separate by ulceration. If this method be attempted on a prominent tumour of the size of a filbert, or larger, it possibly may not succeed entirely, and a repetition may be requisite (indeed, as many as 120 needles have been used by Lallemand), or perhaps, in the long run, the surgeon may be induced to try some other plan: moreover, it may be imagined that in instances requiring so many needles as 120, both surgeon and parents might naturally doubt the efficacy of the practice. That large tumours may be cured in this way, however, there need be no doubt; and one of the most remarkable of the kind which has ever come under my notice was treated by my friend Dr. Maclachlan, late of Chelsea Hospital, while he was assistant-surgeon in the 79th Regiment. The disease was chiefly connected with the temporal, occipital, and auricular arteries, and some idea of its condition may be formed from the accompanying sketch, fig. 75.

The particulars of the case were published in the 51st Volume of the
Edinburgh Medical and Surgical Journal, and I need not here state more on the subject than that I assisted Dr. Maclachlan when he introduced the needles for the first time (four in number), and that the cure was accomplished in seven months by careful pursuance of the same plan, eight needles being all that were required throughout the treatment. Not long since I had an excellent result from this style of operation, in a young female patient at King's College. A most extensive vascular tumour occupied the site of the mamma, and so involved the gland, that it would have been impossible to remove the disease with a knife or ligature, without sacrificing this important organ. By applying needles and ligatures over them at various places around the mass, most of the large vessels were obliterated, and a most satisfactory cure followed, with the mamma uninjured.

Some years ago an exceedingly interesting case of this description came under my care. A young woman about twenty-two years of age became a patient of my friend Mr. Robert Storks. The vessels of the scalp, particularly on the left side, were enormously distended, as may be here seen (fig. 76). Both arteries and veins were involved, but the veins seemed most affected. The vessels were slowly increasing, and the girl felt unfit for her usual occupation as a housemaid. Ligature of the common carotid was resorted to by Mr. Storks, and considerable improvement followed. Pressure on the scalp, by means of elastic caoutchouc bands, had now more effect than before; but still the veins continued of vast calibre, and long arterial pulsation could again be felt. The patient could not resume her duties, and earnestly desired that, if possible, something more might be done. She then came under my care in King's College Hospital, when I adopted the plan above referred to. Long needles were passed under and through the vessels at various prominent points. These were sufficiently strong to bear the pressure made by twisting strong threads about them over the included vessels and scalp, and it was resolved to leave them until there seemed necessity to interfere. At some points sloughing
occurred; elsewhere ulceration loosened the needles, and throughout the parts interfered with there was inflammation and induration. In about three weeks a result took place which I had anticipated; violent hemorrhage came—happily during my visit to the hospital. Pressure with fingers was adopted, until the old needles were withdrawn and fresh ones introduced; when threads were again applied and the bleeding was arrested. Further inflammation and obliteration of vessels ensued; hemorrhage, which occurred on several subsequent occasions, was arrested in a similar manner by my assistants, who were constantly on the alert at periods of danger, and the result of the practice was the total obliteration of all the formidable affection, with firm cicatrices marking where the sloughing and ulceration had been. The patient, when I last saw her, many months after she had been under treatment, was quite well, and able for any ordinary occupation.

The practice above described was certainly attended with considerable hazard, both on account of the inflammation as well as the hemorrhage, and it was not without misgivings that I adopted it. But the case seemed otherwise hopeless, and the previous obliteration of the common carotid led me to trust that such bleeding as might occur could be controlled. Without this preceding step, it may be doubted if the result would have been equally successful; and I am, therefore, disposed to attribute the satisfactory issue to a combination of the two methods, viz., first, the obliteration of the main arterial current towards the disease, and then the destruction of the vessels in its substance.

The above plan of treatment may be considered a modification of a method pursued by Mr. Keate, Sir B. Brodie, Mr. White, and others. These gentlemen introduced the needles for the purpose of giving a good purchase for the threads, so that they might be drawn sufficiently tight to cause strangulation and sloughing of the mass. The method which I suggest, and which I have followed occasionally for the last thirty-five years, has for its chief object the compression of the vessels, the inducement of a certain amount of inflammation and consequent obliteration of vessels, without any material destruction of skin or other tissues. It may, perhaps, be considered a less severe proceeding than removing the whole mass by strangulation.

A seton, carried through the centre of such diseases, as recommended by Mr. Fawdington, of Manchester, has been known to excite high inflammation and obliteration. A needle should be used for the purpose, and the thread should be sufficiently large to fill up the track of the wound, otherwise troublesome hemorrhage might be the result. In some instances, when trying this plan, I have subsequently, in the same tumour, observed that two or three single threads, passed through different parts of the disease, by means of a common sewing needle, have had a more decided influence than the large single cord composing the seton.

Two or three subcutaneous incisions will have the double effect of destroying some of the enlarged vessels, and exciting inflammation afterwards. The blood which escapes in these instances will press
upon the vessels forming the tumour, and being in a manner infiltrated amongst them, may cause more extensive inflammation.

Sir Benjamin Brodie advised that a small opening should be made from the surface towards the centre of such growths, and that a probe coated with lunar caustic should then be introduced. It has been recommended to push the nozzle of a small syringe into the mass, and thus introduce a quantity of irritating fluid, such as tincture of iodine, or perchloride of iron, so as to excite the desired amount of inflammation: —but there is scarcely an end to the various methods by which this process may be induced.

The fearful account which John Bell gave of certain attempts to remove these tumours by the knife, had, probably, a strong effect in preventing any interference with them in this way; and, indeed, unless the surgeon can make sure of the limits of the disease, he will seldom be justified in adopting such a course; for although an energetic practitioner may arrest the bleeding which is the immediate and certain result of cutting into such tumours, and dividing so many enlarged vessels at the same time, there may be a greater quantity of blood lost than prudence would deem right. I have seen a free incision made into a large tumour of this kind on the forehead; and although the bleeding was copious for an instant, the surgeon was so well prepared with proper pads and bandages, that comparatively little blood was lost. Here the operator had previously assured himself that the bone was sound behind; and as the head was fully developed, and the patient beyond infant years, there was no difficulty in keeping up efficient pressure.

If the limits of the disease are well defined, there need be little dread of bleeding; for incisions in the healthy parts around will not give rise to greater trouble than under other circumstances. The principal objection to this plan is the size of the wound and consequent scar; and, besides, there are few instances in which it is admissible.

In the course of years I have had reason to doubt the correctness of John Bell's views, as applied to all growths of this kind, and though I still advise caution in cutting into such masses, I have seen instances where incisions may be made with little more bleeding than from ordinary cellular tissue. These have been cases which I was about to treat by incision and ligature. In some I have thought it advisable to apply the ligature to the deep part of the tumour, and in others I have continued the dissection so as to remove the greater part of the substance. Some years ago I had in King's College Hospital a young lad who had been declined as a recruit for the army, in consequence of a vascular growth over the outer malleolus on one leg. The tumour was chiefly venous, and disappeared rapidly on pressure. It covered an extent equal to the diameter of an orange, and at its most prominent part was about three-fourths of an inch in thickness. Here, after making a crucial incision, with the view of raising the skin from the mass, before introducing the threads to cause strangulation, I found the escape of blood from various points of the surface so trifling, when I had actually cut into the substance of the tumour,
that I was induced to cut deeper, and so remove the greater part of the disease with the knife. Such parts as were left behind, I expected would be obliterated by the subsequent inflammation. The result was ultimately satisfactory, although slight secondary bleeding occurred on several occasions, and the inflammation for a time was not of a healthy character. In several other instances, in other parts of the body, I have seen subsequent hemorrhage and severe inflammation follow, and, on the whole, I cannot recommend this partial kind of excision. I have referred to these instances chiefly with the purpose of showing, that there need not be that great dread of hemorrhage in many of these cases, such as must be entertained by all who have read John Bell’s descriptions. The examples to which I refer, it must be remembered, however, were chiefly venous tumours. When the arteries have been in greater size and number, the bleeding has been more remarkable.

To avoid the danger of bleeding, it has been a frequent custom to encircle these tumours with a stout thread, which is drawn sufficiently tight to cause strangulation and sloughing. This has been done by Sir Benjamin Brodie and others, as above referred to, by means of needles passed through or under the disease, and strong thread twisted round, with tightness sufficient to cause the whole mass to slough: and it has been a common practice to push a needle through the centre of the disease, to convey a double ligature across, one of which has been tied round the root of one half of the tumour, the other round the opposite half, both including skin as well as disease. These modes are very efficient, but painful, and liable to objection from the size of the scar which must be the result; besides, if the base of the tumour is broad, complete strangulation may not be effected at once, and new threads must be had recourse to. Sometimes a contrivance has been used, whereby the amount of pressure could be regulated by a screw, and so, as the threads have got loose by the decay of tissues, the requisite constriction has been again applied. The plans alluded to include the destruction of the skin included within the needles or nooses; but it has been proposed to introduce ligatures under the tumour, so as to strangulate the diseased mass without necessitating the loss of skin. Mr. Adams, of the London Hospital, Mr. Birkett, and others, have published cases of this practice, and if a cure can thereby be effected without destruction of the cutaneous surface, the method seems worthy of more extensive trials. For many years I have tried this method frequently, and am most favourably impressed with its advantages.

A method by incision of the skin and the ligature was most successfully resorted to by Mr. Liston. By convenient incisions the skin was elevated from the circumference of the tumour; needles and threads were then introduced, and the diseased mass was treated in the manner above described. This plan has the advantage of preserving a larger portion of skin, and also of allowing the noose to be drawn more closely in contact with the disease, which is thus effectually compressed at once. The surgeon’s judg-
ment must indicate the proper incisions and flaps to be made on such occasions. If the tumour involves part of the skin, the knife should be so carried as not to interfere with it; but generally towards the circumference of such growths it is perfectly healthy, and can be raised without much danger of cutting into the mass. The needles for such operations may be similar to those represented at p. 34, and I would especially recommend that shown on p. 35, which, being set in a handle, can be used with greater force and precision. Common ligature thread is not strong enough to permit a sufficiently firm noose being drawn, and small twine or whipcord will be found more advantageous. Instead of one needle only being used to carry across a double ligature, another, armed in a similar manner, may be run at right angles with the first; and thus by four threads being present, more complete strangulation may be effected. Four threads were used by Mr. Liston, and these, by being knotted to each other, encircled the tumour, and at the same time cut it into four portions.

When it is desirable to get rid of a tumour at once, I give the preference to the plan recommended by Mr. Liston, wherever it is practicable. The method which I follow is a slight modification, and, if I may presume to say so, an improvement upon that alluded to. I proceed thus: I take a common surgical needle (p. 34), proportioned in length to the diameter of the tumour, and, having threaded it with thread of proper strength, I thrust it across the base of the swelling: the thread doubled being drawn some eight or ten inches through, one portion is carefully selected; the part next the eye of the needle is cut across about two inches from the metal; the free end of the same on the other side of the tumour is passed through the eye of the needle; then the latter is thrust across the tumour again, at right angles to its first course, and when free of the skin, the threads are disengaged, and the needle is withdrawn, whereupon, by seizing the proper ends, it will be found that the requisite constriction can be effected by tying only two knots instead of four. This description will perhaps be better understood by the accompanying figure (77). I published a particular account of this kind of noose in the Edinburgh Monthly Journal of Medical Science, for 1847. At that time I was in the habit of using the needle fixed in a handle (p. 35), but latterly I have preferred the common surgical needle as above described. Instead of making the incisions before introducing the

---

![Diagram](image-url)
needles, I leave the skin entire, with the exception of the punctures with the needle, until the threads are adjusted. I then make, with a scalpel, incision from point to point, draw the loops into two of the fissures thus made, and tying knots on the free ends, and sinking them in the other two incisions, by drawing, so strangulate the central portion of skin and the mass at the same time. By reserving the application of the knife until the ligatures are passed, I imagine that less blood is lost than would otherwise be the case. In certain instances, when the skin is involved in the disease, it answers no good purpose to preserve any of it. In such cases the nooses may be drawn upon the skin, but I believe that it causes less suffering, and probably expedites the separation of the slough, if a slight cut be made through the skin exactly where the nooses would fall upon it. When the thread is tightened, it sinks into these notches, and perhaps a more exact limit to the part to be strangulated can thus be made at the will of the surgeon, than by drawing the thread directly upon the surface of the skin. The mass generally sloughs in about five or six days after this operation. A comparatively large gap is thus left, but in a few more days, as granulations spring up, and by drawing the edges together by adhesive plaster, the sore diminishes in size, so that, when cicatrization is perfect, a wonderfully small scar remains. Of all methods, where it is needful to cause sloughing, this is the one I now most prefer.

Instances occasionally occur, where even the above method cannot be resorted to with propriety. Some years ago I treated a case of this disease in a lad about the age of puberty. The tumour was situated on the outside of the thigh, midway between the trochanter and the external condyle; it was but slightly prominent; and although its diameter in all directions seemed three or four inches at least, its exact limits could not be made out. On all sides large pulsating vessels could be felt passing into it, and there was every reason to suppose that the affection was deeper than the aponeurosis. It had been present from infancy, but had only lately come near to the surface, where several small ulcers had formed, from which the blood flowed copiously on any unusual effort being made. Being unable to commence active occupation, the patient was willing to submit to whatever plan of treatment might be advised. Excision seemed out of the question, incision equally so; and the breadth, flatness, and supposed depth of the affected mass, precluded any attempt to cause the tissue to slough away with ligatures. The position was not favourable for pressure, and vaccination or caustics seemed insufficient for the bulk of the disease. I used a variety of needles in the manner already described, and with some good effect. Still, however, the formidable part of the disease remained. I then passed several large cords, as setons, and these, too, had a favourable influence, but the affection was far from being cured. Ultimately, finding that these measures excited far less inflammatory action than might have been expected, I introduced, by means of long slender needles, a variety of single threads in all directions. More severe inflammation ensued, and when
the swelling thus produced had subsided, the tumour was smaller, and firmer than it had ever been; there was less distinct pulsation in it, and a thrill, which was perceptible previously, could not now be detected. When the various apertures on the surface had firmly cicatrized, the boy was allowed to move about as he thought proper; and after watching him for more than a year, I could not perceive any indication of the disease being likely to trouble him further. Several small vascular points were still visible on the surface, but these caused no uneasiness, and I believe, had the patient been anxious, might have been advantageously treated in a similar manner. As it was, the lad, from having been unable to walk without dread and danger of bleeding, now felt equal to any fatigue, and called to show himself previous to entering on the active duties of a sailor.

Of late years a disease named Aneurism of Bone has been a good deal spoken of; and my friend Dr. Handyside, of Edinburgh, has written an excellent treatise on the subject. I have often thought that it is no other than aneurism by anastomosis, modified in some of its symptoms and conditions by the peculiar texture in which it is situated. It has hitherto been observed chiefly in the interior of the upper part of the tibia; and as it is evident that few of the local measures referred to in the preceding pages could be of any service in such a situation, unless ligature of the femoral artery checked the disease, amputation would be the only resource. If the surgeon thought of scooping out the disease, as he would a caries, in the manner which will be described with reference to the last-named condition in the tibia, I would recommend that both he and the patient should be prepared for the necessity, which might immediately ensue, of amputating the limb above the tibia. The disease has been found to extend so deep in the interior of the bone, and also to cause such expansion and swelling, as to be far beyond reach from such local measures. Ligature of the femoral has been known to be successful; and, judging from the favourable issue of deligation of the carotid for similar tumours on the head, by Travers, Dalrymple, and many subsequent operators, out of whom I may single Dr. Mussey of America, and Professor Kuhl of Leipzig, who have even tied both carotids for such a disease on the scalp, I imagine that it would be the most judicious practice to try such a method, before resorting to others which more immediately implicate the safety of the limb. A most interesting case, in the lower part of the femur, supposed to be of this kind, is related by Mr. Hargreaves of Burnley, in the Medical Gazette for 3rd June, 1842. The femoral artery was tied, and apparently with good effect, when, unfortunately, the patient died from an attack of purpura before the efficacy of the operation could be considered as fairly tested.

On the whole I feel bound to state that the result of my experience leads me to think that deligation of the main artery, in such cases, is not so frequently required as I was led to imagine from my early education.
CHAPTER XXII.

TUMOURS.

The term Tumour is in general use amongst surgeons, to indicate swelling on any part of the body, under almost any circumstances; thus, a swelling in the scrotum, from whatever cause it may arise, whether from enlargement of the testicle, varicocele, hydrocele, or hernia, is usually called by the name of tumour: effusion into the synovial capsule of the knee-joint is often thus designated, too, as well as the different forms of white-swelling. Enlarged tonsils, enlarged thyroid gland, enlarged prostate, local enlargement of veins (varices), are also spoken of under this general title. Strictly the term is applied to instances of adventitious formations of a prominently local character, which may or may not resemble the natural textures of the part or of the body. For example, if a person grows very fat, although the whole body is thus augmented in size, we do not apply the term tumour; but if there is an extraordinary secretion of this fluid in a particular region of the body, constituting a distinct swelling, separated from the surrounding fat and cellular texture by a capsule of the latter tissue, we apply the term tumour,—fatty or adipose tumour, in consequence of its resemblance to common fat. Again, a growth may form which has no resemblance either to the part in which it has arisen, or to any healthy organ, whilst in other instances there may be a degree of resemblance to some normal substance, as in the medullary tumour, which may be met with in muscle, bone, or any other texture.

However laudable it may be to endeavour to give precision to the word tumour, I doubt if surgeons will ever give up the terms of tumour of hernia, tumour of hydrocele, tumour of hydrocephalus, tumour of abscess, and such like. Dr. Warren, one of the latest authorities on the subject, has been content to leave the term as he found it; and, indeed, except among excessive sticklers for remarkable precision of language,—who are not on that account, however, to be considered the most precise or intelligent authors or practitioners,—I have never seen any difficulties as to what condition the name of tumour was or was not applicable.

Tumours vary in size, shape, position, and organization, to an endless extent. The size may be so small as to be scarcely appreciable, or so large as to equal the aggregate of the whole body or more. The shape is exceedingly variable,—round, flat, oblong, pyriform, and so forth; they may occupy any part or texture, may be on the surface of the body or deep-seated, and their organization and physical appearances are such, that even the most experienced pathologist frequently meets with examples which he may not have observed before.
Some tumours are of a solid fleshy character throughout, such as were described by Mr. Abernethy under the title sarcomatous; others consist of a bag or cyst, which contains fluid,—the encysted species of the same author: occasionally there is a sort of combination of the two, for there may be one cyst or more in a tumour whose general character is sarcomatous, and in another case a cyst may ultimately assume the appearance of a more solid growth. Indeed, according to Dr. Baron, and also certain modern doctrines founded on microscopic researches, there are grounds for supposing that even the most solid tumours are originally formed of cysts,—cells,—cytoblasts, as they have recently been named. But for more precise information on such views, I may refer to the volume of interesting lectures on tumours by Mr. Paget, as delivered by him at the Royal College of Surgeons.

For practical purposes, the arrangement of tumours into those which are malignant, and those which are not so—benign, as they are called—is perhaps the most useful. I here use the term malignant as it is generally applied to such diseases as scirrhus, medullary sarcoma, and melanosis. These are maladies which, if not interfered with by the surgeon, are certain to get worse,—to contaminate the system, (if, indeed, they are not already local effects of constitutional disease,) and to be the direct cause of death. The non-malignant, or benign tumour, is exemplified in what Abernethy called the simple sarcoma, or the adipose sarcoma, the cystic sarcoma, and the painful subcutaneous tubercle, described by Mr. William Wood: the different forms of encysted tumour also come under this title, whether the cyst contains a thin fluid, like serum, or a thick curdy material—whether it be wen, ganglion, meliceris, atheroma, or steatoma.

The opinion that such a disease as scirrhus is entirely of a local character in its early stages, seems to gain few additional advocates in the present day. Dr. William Budd, of Bristol, has ably advocated this view in a paper which was read before the British Medical Association, and afterwards published in The Lancet for May, 1842. Surgeons (even some of those inclined to deem it hereditary, and therefore constitutional) may be said always to have acted on such an opinion, and, as soon as the real character of the disease has been recognised, have resorted to an operation for its removal, under the impression, that if in reality local, and excised at an early period, there is less chance of the system being contaminated, or, in other words, a similar disease showing itself in another and probably distant part of the body.

It is often an important and difficult question to determine when tumours are malignant or the reverse; and the most experienced cannot always do so on the living subject. When the tumour is removed there is less difficulty, for there are few who cannot recognise the difference between the two kinds. The scirrhouis, medullary, and melanotic growths can be detected at a glance: the fatty and encysted as readily, and the distinctions between them and those first named can, with equal facility, be made out. There are certain tumours, however, especially some of those in the bones, whose particular cha-
racters as to malignancy, or otherwise, cannot so easily be appreciated, even when removed from the body, and often in such cases the most accomplished pathologist must be content to watch the issue. If there is no return of the growth, he concludes that in all probability the disease has not been malignant, and vice versa.

The symptoms do not always indicate the characters now under consideration. For instance, pain is not a test of malignancy; for the most painful of all, perhaps, is the subcutaneous tubercle, which, however, is not malignant; whilst, on the other hand, medullary sarcoma, one of the most malignant of all growths, is not characterized by remarkable pain. The peculiar prickling lancinating pain of scirrhous is often a good test of the disease; but frequently such tumours are met with in which this symptom is by no means conspicuous. Rapid growth is probably a more certain test of malignancy; but many exceptions to this may be met with also. I am most inclined to take as clear indications the apparent effect which tumours have upon the constitution, and the extent of their connexions with the neighbouring parts. If a patient, after a growth has existed for some time, gradually loses flesh, becomes pale and languid, has constant uneasiness (if not pain) in and around the part, I consider these good grounds for suspicion that the affection is malignant; and if, in addition, the local disease has no distinct limits, (in other words, if the exact line of separation between the sound and affected parts cannot be made out,) if the tumour be in a manner fixed, if the skin over it, however much it may be stretched, does not appear healthy, and glide freely upon the swelling, and if the latter does not move readily on the subjacent parts,—if, added to these, the whole, or the greater part of the thickness of a limb, or wherever the disease may be, seems to be more or less involved, there need be little doubt that the affection is malignant. Some objections to these general characters will at once be perceived,—as, for example, a tumour of bone cannot be moved like one in soft parts; and, in certain instances, there are additional characters which indicate peculiar diseases, as the ulceration in the latter stages of scirrhous, or the bleeding growth in fungus hematomata.

My own experience coincides entirely with that of every unprejudiced observer, that when malignant growths are removed with the knife their return is but too likely; nevertheless, as excision gives the only chance of security—a point on which most parties seem to agree—an operation should always be resorted to, provided the knife can be carried beyond the supposed limits of the disease; and, moreover, I deem it one of the duties of the practitioner to urge the patient to submit to such a proceeding. Many imagine that one time will be as good as another for such a purpose, and most will be pleased to put off the evil day; but if our professional education does not tell us how to cure such diseases by less harsh measures, it enables us, at all events, to foresee the threatened danger, and to warn the patient of it at an early period.

When the growth is supposed to be non-malignant, there is less imperative necessity for interference. Thus in a fatty tumour, or one
of an encysted character, the decision may be almost allowed to rest with the patient. The latter form is frequently met with on the scalp, and the fatty often acquires an immense size, so as to produce marked disfiguration, and perhaps inconvenience, both from its bulk and weight. If, however, the patient is willing to put up with such conditions, it is not incumbent on the surgeon to press an operation, as he should in an instance of malignant affection.

In all cases of a doubtful nature, if the circumstances are otherwise favourable, I believe that the surgeon best does his duty who recommends an operation. In inculcating this practice, I by no means wish it understood that the knife is to be the immediate expedient; on the contrary, in the early stages of tumours, whenever such measures can be resorted to as may be supposed to cause absorption, they should have a fair trial; but when such plans fail, as they will almost invariably do, and if there is reason to suppose that the further continuance of the disease will be detrimental to health, I deem the practitioner highly culpable who still tampers with it, and persists in placing faith in either local applications or constitutional remedies.

Under the supposition that the vessels in a part where tumour first begins are preternaturally excited, it is customary to apply leeches in the neighbourhood; counter-irritation is afterwards resorted to, on similar views which lead to the employment of such a remedy in deep-seated inflammation. The plan of tying one or more of the enlarged arteries leading to the disease, as in the case of bronchocele, and thereby directly cutting off some of its channels of supply, has also been put into execution, probably on similar principles.

The various local means which have been used on these occasions are much the same as those already referred to in describing the treatment of inflammation and some of its consequences, and I need not, therefore, enumerate them again. Iodine is the remedy in which most faith has been placed for the last thirty or forty years; but I am free to confess, and deem it my duty to do so, that I have never in one single instance seen an organized adventitious growth removed by it. I have already stated my conviction that large swellings of serum, lymph, blood, and pus, may gradually disappear,—be absorbed, as we say in common language,—and firmly believe that on many occasions iodine, used internally, but particularly externally, produces more decided effects in some of these instances than any other means we know of. Hydrocele, hydrophthalmia, effusions into joints, cysts (though rarely), enlargements of glands, such as the lymphatic or the thyroid, even gelatinous alterations of synovial membranes, will all disappear under the use of iodine; but I may challenge any one to produce a single case where an exostosis, a scirrhous, a medullary sarcoma, or a fatty tumour, has been removed by its influence. I am myself a great admirer of iodine in its different forms, and often wonder whether the remedy has not suffered in character from the overweening confidence of some of the zealous advocates for its supposed extraordinary powers: in numerous instances where improvement has taken place during its use, I fear that, as in the case of many other so-called specifics, there
has been too little note taken of those changes, both local and constitutional, which are the results of time and other circumstances.

Operations for the removal of tumours may be amongst the most simple or amongst the most difficult and dangerous which the surgeon is ever called on to perform. The smallest possible amount of skill or manual dexterity may suffice in one instance, whilst in another, anatomical knowledge, facility in the use of instruments, judgment to plan and courage to execute all the steps of the operation, are indispensably necessary.

Encysted tumours may be operated on in a variety of modes. If of that kind commonly known under the name of ganglion (most frequently seen about the wrist and ankle), and if the cyst is not dense and strong, a little pressure with the fingers, a smart blow with the knuckle, or with a book or other solid substance, will cause it to burst; the fluid will be extravasated in the surrounding cellular texture, and then absorbed; some inflammation will be excited, partly by the injury of the cyst, and partly, perhaps, from the extravasation; adhesion and obliteration of the sac may occur; and so the disease will be got rid of, and in the course of time no vestige of the sac may remain. Sometimes the sac cannot be burst, and then a grooved needle may be pushed into it at one or more points, or a subcutaneous incision may be made to allow the fluid to escape into the surrounding texture. In either of these modes it may be well to scratch the interior of the sac, so as to induce inflammation; and whether these plans are followed, or the tumour is burst, a pad and bandage should be applied to keep the surfaces of the cyst in apposition. I have occasionally, in large collections of fluid in the sheaths of the tendons about the wrist, successfully introduced a single thread, much in the manner recommended for the treatment of aneurism by anastomosis. Sometimes tincture of iodine has been thrown into these cavities; and numerous other methods have been followed, all of them with the view of exciting inflammation within. Cysts often require to be freely laid open with the knife, and treated as we would an abscess after incision: the housemaid's knee and miner's elbow, which in their uninflamed state are in some measure like the cases under consideration, may be treated in this manner; but the sac, especially over the patella, is often so thick, that it is better to dissect it away entirely; indeed, in most instances, with the sac in this condition, it is the best mode of procedure. In cutting out such tumours, the sac may either be laid open, and then partly torn and partly cut away with the knife or scissors, or it may be removed entire. One or other of the latter modes is required for the treatment of wens, for which excision is deemed necessary; and in all such instances when the contents are supposed to be of a nature that absorption will not likely occur, it is best at once to make use of the knife. When encysted tumours are of considerable size, it may be proper to remove an elliptical portion of skin, but as a rule I recommend leaving all this tissue, for however loose it may be at first, it will almost invariably contract to its normal state. Whenever an operation is undertaken for a cyst, the whole of the bag should be carefully re-
moved, if it is possible to do so with propriety. When the cyst seems loosely attached to the neighbouring textures, I believe that it will generally be best to open it, turn out the contents, and then to scoop it out with the handle of the scalpel, or to seize and tear it away with well-pointed forceps (p. 5), or to use the scalpel to divide the adhesions; but if there is much dissection required, it may perhaps seem best to keep it entire; and even when it is accidentally punctured, a thread may be passed round the opening to prevent escape of the contents, which, if not confined in this way, might prove more troublesome than blood, by obscuring the course of the knife.

For the excision of solid tumours, the surgeon must be guided by their shape, size, situation, and connexion, in forming his plans. Rules will be afterwards given as applicable to special cases, and at present I may refer to the description of the proceedings for the removal of the mamma, as containing a variety of instructions which may serve for operations on tumours in other parts of the body. In general it is necessary to cut all the connexions; for, with the exception of certain kinds of cysts above alluded to, and the example of the adipose tumour, both of which may be torn out after the skin has been divided, the knife cannot be dispensed with. The last-named growth is usually so loosely attached, that there is seldom any trouble in separating it with the handle of the knife, or with the fingers. It should at all times be an object with the surgeon, in such proceedings, so to plan his external incisions as to leave the smallest possible amount of scar afterwards, and, in cutting the deeper parts, to avoid important organs as much as circumstances will permit. He should not, however, so limit his incisions through the skin as to hamper himself in future stages; and in removing malignant growths, he ought to bear in mind, that it is better to sacrifice a considerable portion of the surrounding healthy parts, than to leave the slightest vestige of disease in the wound,—the operation here being done to save life.

The method of removing tumours by ligatures, caustics, or cautery, is, in general, very objectionable. In some instances of malignant nature, or where it is deemed unsafe to carry the knife beyond certain limits, such measures are occasionally resorted to; but the practice cannot be recommended excepting under peculiar circumstances. Aneurism by anastomosis, for example, is perhaps best treated by a very partial use of the knife; and deep-seated growths, such as internal hemorrhoids, ought rarely to be meddled with by cutting instruments; but when there is no hazard from bleeding they should be used in preference to any other means. A strong escharotic, such as the corrosive sublimate, oxide of arsenic, chloride and sulphate of zinc, usually, I believe, form the principal ingredient in nostrums which are said to cure cancer and other "incurable" diseases; the material (generally in the form of a paste) converts the tumour, or diseased part, into a slough, and oftentimes the malady is thus rooted out by a haphazard proceeding, to which a rational medical man would hardly consider himself justified in submitting his patient. I have known examples of this kind, where a large portion of the
integuments of one side of the chest has been destroyed in this way:—
cancer, mamma, and all, have dropped off as a slough, and the large
sore has ultimately healed. It is notorious, however, that death has
often been the result of such empirical practice, and few surgeons
would dare to treat an extensive disease in this manner. One case I
deem worthy of notice here: a man had a tumour of malignant aspect
in his cheek; an eminent and highly qualified surgeon removed it with
the knife; the disease returned,—was again operated on by the same
hand, and once more appeared; the patient, unwilling to subject him-
self to another cutting operation, allowed an escharotic to be applied by
a non-professional person, which effected a complete cure. Doubtless
in this instance the operator had been too sparing in his incisions. I
once operated in a similar example for the third time, and succeeded
in completely removing the affection. Sloughing sometimes occurs
spontaneously, and performs a cure where the surgeon's calm judgment
has been against interference: I know of two instances of supposed
malignant disease in the upper jaw, where the whole parts have
sloughed spontaneously, and perfect cures have followed.

The treatment of tumours, particularly of cancer, by means of
caustic, has attracted considerable attention of late years. Spasmodic
periods seem to arise from time to time. Generally the empiric takes
the initiative, and then weak-minded professionals fall into rank—
charlatan, doctors, and patients vie with each other in praise of the
nostrum. At last the delusion fades away, or gives place to a new
"infallible," whose story runs the same course. The latest "thing"
in that way has been heretofore respectable Acetic Acid!

CHAPTER XXIII.

ON DISEASES OF BONE.

Any one familiar with the subjects already noticed in this volume,
may, in some degree, be able to appreciate many diseased condi-
tions of bone, and so much will be found in future pages on the
subject, that little notice is required of it here. In accordance, how-
ever, with the plan of my work, I think it well to make some general
remarks in this section of the arrangement, which may save repetition
in future chapters.

The bones are so well protected from external injury, that, unless
great violence be applied, they rarely suffer. The periosteum and
other contiguous tissues suffer more, however, from external violence
when it is applied on a part where bone is superficial than under other
circumstances. Thus, a blow over the tibia, or on the cranium, is
more likely to prove injurious to such tissues than a like force on parts
with a thicker covering of soft material. When the periosteum suffers,
the bone is more or less implicated, and evil in proportion may be the
result. External violence may be followed by trivial results, or by serious mischief, in accordance with the amount of injury and the natural or acquired state of the constitution. Generally in healthy persons, even the highest degree of violence, such as fracture, will be satisfactorily repaired; but in certain instances, much evil may result from violence far less than that which may occasion fracture. Many of these evils are such as can be duly appreciated by any one already familiar with the doctrines of inflammation. This disease itself can be readily recognised in the osseous tissue, and most of its results, modified by peculiarities, can be appreciated as easily as in other structures. But the effects of injuries, or wounds, need not be dwelt upon here, as there is a separate chapter on fractures elsewhere in the volume. Diseases of bone of spontaneous origin, or from causes which may or may not be readily appreciated, are generally more difficult of management than those arising from some apparent source: thus, the temporary inflammation from a blow, or even a fracture, is of more certain amount and duration than that which has a spontaneous or constitutional cause. It is comparatively rare for inflammation arising from an external injury to be followed by much evil, and experience leads us to anticipate the best that can befall in such cases; but in inflammation or analogous action of spontaneous origin, it is not always in the power of even the most experienced to foretell all that may happen.

Inflammation resulting from an injury, usually yields to such remedies as are of service in like conditions in other tissues. Local blood-letting is of great advantage, as, from the density and unyielding nature of the structure, pain is usually very great. It is customary for writers on this subject to draw distinctions between inflammation of the bone and the membranes connected with it, and so reference has been made to inflammation of bone by itself (ostitis), of the periosteum (periostitis), and even of the medullary membrane; but, although it must be admitted that in certain cases the marks of disease may appear more distinct in one structure than in another, especially after removal of the part, or death, it is seldom that the practical surgeon can perceive such distinctions on the living body. Indeed it is hardly possible to conceive one of these tissues being very palpably affected without another suffering to a greater or less extent also. The vessels of the one are so much the vessels of the others, that such a condition as a distinct inflammation of one structure without the contiguous being affected, seems to me almost impossible.

In recent times the term "osteomyelitis" has been applied to this seeming compound of inflammation of periosteum and of bone—particularly by French army surgeons, and the fashion has been followed, unfortunately, I think, by our own army men—a new name for a well-known disease. The fault, if such it be, lies, I imagine, in part with the older anatomists and pathologists, who did not bear in mind that periosteum is as much in a bone as around it.

In some cases inflammation is limited to a small extent, in others a whole bone may be affected, and, again, one or more of the bones may
suffer at the same time. In such instances as the latter, the disease will most likely be of constitutional origin. When there is thickening of periosteum or bone at one or more points, the condition is usually called a node, and the term soft or hard is applied in accordance with these qualities. In a soft node the disease is chiefly in the periosteum, on the surface; in a hard one, vessels within the bone—that is, of the internal periosteum—are principally affected.

If inflammation of bone be the result of a blow, and if there be great pain, an incision through the periosteum over the extent of the disease may be productive of great benefit; but there are not many localities in which such practice can be resorted to. Over the tibia I have seen it of great service; and if, as occasionally happens, a little matter forms between the outer periosteum and bone, the incision is of much importance. Such an incision may include skin and periosteum equally; but I have seen a subcutaneous division of the periosteum answer admirably, while the subsequent annoyance of a large wound on the skin has been avoided.

In most instances, if inflammation of periosteum or bone does not end in caries or necrosis, there is a natural tendency for the disease, after a certain degree of development, to get well of its own accord; if not, and in the absence of either of the two conditions above named, a chronic action results, probably from some inherent disposition in the constitution, and it is usually more persisting, and less amenable to treatment than the other. Often in such cases there is great thickening of parts, in one mostly in the outer periosteum, in another chiefly within in the bone. When the latter part is affected thus, there seems in some instances a general expansion of structure without much deposit of new bone; sometimes there is great consolidation of tissue without enlargement, but perhaps the general effect is both enlargement and addition in substance. In some cases this goes to a great extent, so that a tibia, a femur, or most of the bones of the body may become twice their natural weight and size. Such changes are seen only in the thickness of a bone; the length is rarely, if ever, affected.

In some instances the additions from inflammatory action are chiefly (if not entirely) on the outside of a bone; in others in the cancellated structure, and occasionally the medullary cavity is nearly if not entirely filled up with the deposit; but it rarely happens that if one part is much affected another does not suffer more or less also. In some of these cases great pain is experienced from first to last, while in others there is very little. One person may move about with tolerable facility, while another is in such perpetual discomfort or pain as to be unfitted for the ordinary duties of life. In certain instances suppuration is present, with its concomitant evils, and the disease is then so much the more severe. The tibia and the bones of the cranium seem peculiarly liable to such thickenings.

Usually in chronic inflammation of periostecum, or of bone, there is some faulty state of the constitution: perhaps a strumous habit by itself; or possibly—indeed more likely, conjoined with the constitutional effect of hard living, of syphilis, or of mercury. In most of such cases,
the exhibition of alteratives and tonics will be of great service, and where there is belief in specifics they are freely used. If mercury seems to be the cause of mischief, then it is not, or at least should not, be used further; but when this is not so clear, it may be used in many instances with much advantage. Generally it is given in small doses, to act rather as an alternative than with the more characteristic effects of this mineral. Perhaps the bichloride is the preparation most in use in such cases: sarsaparilla is much valued; so also is iodine, and especially the iodide of potassium. Bitter infusions are much in use, too; and these, combined in various forms, conjoined with due attention to diet, pure air, and all adjuncts such as are conducive to general health, are the usual constitutional remedies.

While I readily bear evidence to the striking advantages of certain of the medicinal agents above referred to, it would be unjust not to refer to the influence of the ceaseless agency of time. Often such chronic inflammations appear to resist all medicinal treatment, which is therefore given up in despair, when, in the lapse of months or years, and after the effects of medicine must have ceased, a cure comes about.

In some of the instances above referred to, counter-irritants in their various forms are commonly resorted to, in conjunction with constitutional remedies, and often with seeming advantage, although, upon the whole, I deem them of less service than those which have their influence through the system.

Pain will be the chief cause of distress in most of these cases, and whatever agent has the influence of permanently subduing it may be deemed the most useful and applicable; when pain ceases, the patient will be in a great measure satisfied, and with time and such management as a surgeon knows how to apply, other benefits would result which should satisfy all concerned. There may be a total disappearance of evidence of the previous mischiefs, or the effects may be more or less conspicuous, if not troublesome, throughout life.

When inflammation of periosteum, or of bone, runs to suppuration, there is much hazard of serious mischief—in the outer periosteum less so than in bone, especially if the matter is not in contact with the bone; but if pus is once formed in its vascular canals, or in the medullary membrane, then the case is serious in accordance with the locality or utility of the bone which is affected. When matter forms in a soft node, it is perhaps in many instances a very desirable change, as, by treating the case as an abscess, possibly the course of the disease will be materially shortened. The period for opening such an abscess need not be particularly specified, but if matter forms between the periosteum and bone, and its presence can be detected, an opening should be made at the earliest possible period, not only because this will greatly alleviate pain, but also that it may avert further and more serious mischief. If an opening be not speedily made when matter is formed, there is a risk of the membrane being separated from the bone, and of such destruction of vessels and tissues as to produce caries or necrosis. It is a common error to suppose that the contact of the matter produces the mischief in these cases. It is, I have no doubt,
the deprivation of adequate circulation. When leeches, blisters, and other such agents do not seem to arrest a violent local inflammation in such cases, I believe that the surgeon will often do much good by a free incision even before matter has formed. Perhaps, under such circumstances, a subcutaneous incision would be most judicious. I have seen such treatment on the tibia do all that could be desired. The instance of a severe gum-boil gives fair illustration of the advantages of such practice. In such a case when there is about to be, or has actually happened, a formation of pus between bone and periosteum, a judiciously placed incision is generally of much advantage. If, when the knife is applied, matter has not yet formed, the loss of blood and abatement of tension may prove of great value.

If deep-seated suppuration occurs in bone, the case will probably be much more severe and complicated. There will be more suffering, more uncertainty as to the real nature of the case, and under the latter view, less certainty as to the means of relief or the propriety of applying them. Even in such cases, and when the surgeon may be doubtful as to the occurrence of suppuration, matter will find its way to the surface; but in many it does so through such a narrow and possibly tortuous course, that it is often pent up most injuriously. But there are certain cases where the matter seems to be retained in the substance of the bone without the slightest chance of escape, to the great distress of the sufferer. Particular credit is due to Sir Benjamin Brodie for drawing attention to this subject. When there is reason to suppose that matter is lodged deep in a bone, the surgeon is fully justified in making an opening through the osseous tissue, to let it away. Such cases, it must be admitted, are very rare, and even when they occur it is not in every locality that this mode of treatment can be resorted to. But in the tibia, the results of such practice have sometimes proved highly satisfactory. By making or enlarging an opening in such cases, the surgeon, besides giving free egress to matter, may have the opportunity of getting rid of diseased bone, which may latterly have been the chief cause of continued annoyance. But more will be found on this interesting subject in the section on the lower extremity in an after part of the volume.

A frequent result of inflammation of periosteum, of bone, or of medullary membrane, is the establishment of a remarkable condition, termed "caries," or of the actual death, more or less, of the affected part, when the term "necrosis" is applied,—two conditions which, in many respects, are peculiar to bone, and which constitute the most common of the formidable diseases to which this tissue is subject.

The term caries is very generally understood as implying a condition of bone analogous to that of ulceration of the soft parts. In some respects this may be deemed a correct definition, but it does not seem applicable in all cases. Ulceration of the soft parts, after running a certain course, generally shows a disposition to get well, but in caries this is a very rare occurrence. Perhaps, in reality, this state is more analogous to necrosis of bone, or sloughing of soft parts, than to ulceration; the principal feature of analogy consisting in the circumstance
that a healing process will rarely occur unless the affected portion of bone be separated spontaneously, or removed by the surgeon.

Caries may be met with in any bone, or any portion of a bone. Its most frequent seat is in the softer portions, although it is often met with in the hardest parts. A common locality is in the hands, and especially the feet, where the spongy bones are the frequent seat of this affection. In most cases the disease is preceded by well-marked symptoms of inflammation, although, in some, such preliminary indications are not by any means distinct. In all well-marked cases of this disease, I am of opinion that suppuration is invariably present; and although it is customary to speak of caries being present in certain distortions of the joints and of the spine, wherein there is no external discharge of pus, and, indeed, no well-marked proof of its presence, I am doubtful if the term is properly applied. In some such cases, pus is actually present, and may be found after death, or after removal of the part, and perhaps in some, if not in many such cases, the pus is absorbed in the progress of the disease. But in all such examples the presence of true caries may actually be doubted. The affection may be on the surface of a bone, in its substance, or on its articular extremities. Usually, when on the surface there is comparatively little change in the bone; but there may be some slight thickening, or possibly an excavation with seeming loss of tissue. When in the substance of a bone, there is generally considerable thickening, especially in the long bones, and when on the articular extremity the cartilage will have disappeared, and left the surface in a rougher state than is natural in a macerated specimen of the healthy bone. In true caries, perhaps one of the most characteristic accompaniments is a copious formation of matter giving rise to large abscess, or, should there be openings on the surface, to protracted discharge. If, under such circumstances, the bone can be felt with the probe or finger, and is found to be bare, soft, and friable, there can be no doubt as to the nature of the disease.

But, for the purpose of further illustrating the disease caries, it may be well to contrast it with necrosis, a condition which also requires consideration at the present stage of the volume. This term implies the death of bone, and in most instances this state is preceded by symptoms so analogous to those connected with caries, that they cannot with certainty be distinguished. Generally necrosis attacks the hard parts of bones, although it may, in rarer instances, be found in the soft portions. It has been said that necrosis is never in articular ends, yet every surgeon of experience must be familiar with examples of the kind. It is by no means uncommon in dealing with diseased joints, either on the living or dead body, to find loose portions of dead bone which have been detached from some part of the articular surface. If the probe or finger can be placed upon necrosed bone, the similarity to a corresponding surface in the skeleton may be readily appreciated by a surgeon of tact, and possibly the portion of bone may be felt loose and detached from the contiguous part. But a satisfactory decision from such an examination will depend upon a variety of
circumstances. If the portion of bone be small and deep-seated, the
exploration may be difficult, and not clear in its results. If it be made
at an early period, the surface of the bone may not as yet be sufficiently
uncovered to permit the probe or finger to be run freely against it, or
possibly the dead or dying portion may not yet have been separated
from the living, so that looseness may not be detected. In some cases,
however, the distinction is remarkably clear at a very early period.
Even from the first indication of mischief, the result may be antici-
pated with tolerable certainty. One of the most common causes of
necrosis is injury of bone, especially such as greatly damages the fibrous
tissue in close connexion with it. If the medullary membrane or the
periosteum be extensively destroyed or separated from the osseous
surface, necrosis is almost certain to ensue; or should it happen that a
bone, even though for a time covered by its investing membrane, be
exposed to the air, the membrane will dry or separate from the hard
tissue, and death of the portion laid bare will be the result.

In morbid specimens a grand distinction between caries and necrosis
is, that in necrosis the dead portion whether large or small is like in
all respects to a corresponding portion in the macerated skeleton;
whereas in caries, the bone at the affected part has undergone some
remarkable change: portions seem to have disappeared by interstitial
absorption or by disintegration, and the tissue is more porous, also
lighter, than natural. But such conditions are not so appreciable on
the living body. In many cases necrosis is attended with more swell-
ing than caries; or, perhaps, more properly speaking, there is a far
greater amount of new bone formed in the one than the other. In fact,
this might be taken as a strong characteristic of each form of disease.
In caries there seems a tardy disposition to such action, and even when
developed it is never to a great extent. When in such cases there is
much swelling of bone, it is chiefly from expansion; whereas, in
necrosis Nature seems not content with making new bone to the extent
of that which has been destroyed, but there is often a great redu-
dancy. If there be new bone formed in caries (and this is not always
the case) it is so mingled with the carious portion or the part close to
it, that it becomes a difficult point for even a good pathologist to
determine the distinctions, but in necrosis the new bone is always so
distinct from that which has died that there is no difficulty in distin-
guishing between the two.

The discharge from one condition is usually as copious as from the
other: commonly that from caries is thinnest, and least like healthy
pus—that from necrosis being more cream-like and healthy. Generally
there is the most offensive odour from necrosis; this arising, probably,
more from the dead bone in its moist state, than from the matter
which is secreted from the surrounding parts.

Necrosis may be limited to the surface of a bone, may involve one
side of its thickness or the whole diameter, may implicate a short
length or include the greater portion. It must be admitted as a rare
circumstance, that the articular end and shaft of a long bone are all
involved in this condition at the same time. When a surface of bone
is affected, the term exfoliation is generally applied, and when a thick portion, or the diameter of a bone is involved, it is called a sequestrum. In most instances of necrosis, where the dead portion is allowed to remain long in the body, it is apt (indeed very likely) to be surrounded by new bone. On the new bone next to the dead a secreting surface, like the interior of an abscess, is formed from whence pus is secreted, and various apertures are left, in accordance with the extent of the disease, for the egress of this matter to the surface. It is through one or other of these openings that the surgeon makes the examination of the actual state of the dead portion of bone. To the cavity containing the dead portion of bone the term eloaca has been applied, and the same has also been used to denote the aperture in the new bone. There may be only one such opening or several, and the intervening portions of new bone are often called bridges. Sometimes these openings are very small in proportion to the extent of dead bone beneath; in other instances they are large, or there may be one extensive gap in front of the dead portion of bone.

Perhaps the most striking and sure practical distinction between caries and necrosis is, that in caries the affected part may yet be restored to health, whereas if necrosis be present this never can be, and a cure can never take place until the dead portion of bone is thrown off by Nature, or removed by the surgeon. Perhaps such a view pertains more to the theory of the two diseases than to their actual character, and it is here, probably, that the discrepancy arises in the different opinions entertained as to the curability of the disease called caries. My own opinion is, that a certain form of this disease is so closely allied to necrosis that a cure cannot result without the spontaneous separation and discharge of the affected portion, or its removal by the surgeon. It is to such cases, probably, that the term true caries might be limited, and to all other instances that of ulceration of bone might be applied. These observations are particularly applicable to certain states of diseased joints, when caries is said to be present. At one time, in such cases, the bones may be felt to be bare, the surfaces may be made to grate upon each other, and yet a most healthy action—that of ankylosis, may follow, and here, in all probability, the likeness to ulceration in the soft parts may be deemed unexceptionable; but in other instances, the opposed surfaces will never unite, they will remain for years a source of distress, and if a cure does come about, it will only happen after the spontaneous separation of portions of the surface or their removal by the surgeon. But more will be found on this question in the chapter on Diseases of the Joints.

The treatment of caries and of necrosis must be varied according to circumstances. In the early stages, when inflammation may be deemed the premonitory stage of either, the usual treatment of that condition must be resorted to, and counter-irritation has generally been deemed of much value. When either disease is developed, the latter practice may be given up. It is a prevailing custom in caries to persist in various forms of counter-irritation, but in my opinion the advantage of
the practice may be doubted. In necrosis it certainly is no longer of use. In other cases measures more strictly local are most likely to serve. In necrosis all seem agreed as to what should be done if the surgeon has it in his power; viz., the removal of the dead portion of bone. In many instances Nature does this of her own accord; the part which has died is, when let loose by the disjunctive absorption, elevated by the granulations which form underneath, and gradually carried to the surface, either in this way or by the matter which comes from the granulating surface, when it falls away in the dressings, or is removed by the attendant. But in the majority of instances the loosened portion is so hemmed in by soft parts, or by bone, either old or newly formed, that it does not readily get to the surface, and such cases become chronic in character, unless the surgeon interferes to effect the complete separation. It is here that the surgeon best shows his tact and judgment. Often a difficulty arises as to the proper time of taking such a step. If it be resorted to ere the dead or dying piece of bone be loose there will be a failure; and, again, if it be attempted at a very late period there may be so much new hard bone in the line of the operation that it will be all but impossible to effect the removal of the dead portion. When there is little new bone such operations are comparatively simple. Sometimes I have known the lucky period hit before the new bone had got thoroughly developed, especially in its hardness, yet often the surgeon, who has the skill to plan an effectual operation of this kind, only sees the case for the first time when the new bone is both dense and hard. But almost at any time, provided the circumstances seem such as to justify an operation, success may follow a judicious use of instruments in such cases. If the dead portion of bone can be got away at any reasonable expense of cutting, twisting, and pulling, success is almost certain to follow, for the cavity where the sequestrum has lodged, and the wounds made by the surgeon, soon close up. There is generally considerable bleeding in such operations, and, even in most dexterous hands, they often appear both clumsy and rude. In former years they were frequently attended with so much suffering that they had to be discontinued, but in the present day chloroform is of much service in this department of surgery.

The methods for removing dead portions of bone, as well as the various instruments needful, will be specially referred to in other and more appropriate parts of this volume.

In caries the best local mode of treatment seems to be stimulation, and this is usually effected by lotions, instruments, powders, cautics, or cautery. If the disease be of that kind analogous to ulceration, a cure may result from some very simple measure, such as an alkaline wash, as was recommended by Boyer, but if it be of that sort which I have referred to as more analogous to necrosis, and where the bone when dry has been very aptly compared to a portion of porous lump-sugar, it is less likely that simple measures will suffice. If they do, the affected surface must either be thrown off in gritty particles, or possibly may be covered with new bone, thrown out in the interstices of the affected part, on which a healthy healing surface may be the
result. That such a kind of cure occasionally happens I think very probable, but here I may again refer to the chapter on Diseases of Joints for further observations on this subject. In some instances, instead of the diseased surface coming off in particles, several considerable portions separate and fall away, or may be readily removed. Here the case has clearly become necrosis, and it is in such an instance that the term caries, as usually applied, is probably not correctly used; necrosis would be more appropriate, the instance being one where separation of the dead from the living takes place very slowly. If, after the separation referred to, there be no more diseased bone, the sore will soon heal up, although often, in such cases, the surface is sluggish, and requires a continuance of stimulation. There are many instances where it is best to wait for some such changes as those referred to, but judicious interference on the part of the surgeon may often abbreviate the sufferings of the patient, and there is scarcely any department of surgery in which the superiority of one practitioner over another may be more clearly recognised. This interference may be in various forms and ways: by caustics, cautery, or cutting. It is usually so difficult to apply caustics, either in the form of ointments, pastes, powders, or fluids, with precision, that they do not seem much in favour, especially with those who do not eschew all cutting. The same may be said of the actual cautery. Indeed, with regard to this agent when applied locally in such cases, I have sometimes thought, notwithstanding all that has been said in its favour, that it actually causes further mischief at the time, as it kills the surface to which it has been directly applied. It is by cutting that I think the surgeon will produce the most rapid and probably the most satisfactory results; and if the case be well chosen, with the circumstances otherwise favourable, he may effect in a few minutes what years of time might not bring about. Much has been done within the last thirty years in this department, and in no disease is the conservtive spirit of modern surgery more clearly displayed; for, by proper mechanical execution, and a due reliance on the power of Nature, limbs are now preserved almost in their entire condition—useful as well as ornamental, which would in former times have been consigned to the sweeping influence of the amputating knife. Experience tells me that some minds never can appreciate the nature (I need not say value) of these remarks, yet it must be pleasing to those who earnestly and intelligently watch the progress of surgery to see that such a spirit as that alluded to is gradually, I would almost say rapidly, gaining ground. A mistake or failure, in this mode of treatment, may still be remedied by amputation, the last resource in the surgeon’s power.

I must refer to other parts of this work for particulars, as to modes of performing such operations as are above alluded to, and for examples of the efficacy of the practice as applied in various localities.

In certain instances of caries the disease is deep-seated, and beyond reach, or there may be reasons to deter a surgeon from interfering. Under such circumstances he must be content to uphold the strength of the patient, in expectation that a natural cure may gradually come
about. That such may actually happen even when the last ray of hope has in a manner faded into despair, we have every now and then most ample proof. In the spine, and about the pelvis, hip, and knee, such examples are familiar. In some of these cases absolute rest seems of primary advantage. It is the custom with some to persist in the use of counter-irritants, and issues and setons are exceedingly common, especially over the back; but here I must repeat my opinion, that such practice is of questionable utility; indeed, I believe that it often adds greatly to the patient's distress.

Various points connected with both caries and necrosis, not specially referred to above, and most other diseases of bone, will be noticed in other pages, devoted to the consideration of the practical surgery of the different and individual parts of the frame.

CHAPTER XXIV.

ON INJURIES AND DISEASES OF JOINTS.

Diseases of Joints demand a large share of the surgeon's attention, and some separate notice of such special cases may be most appropriately introduced here. From their locality and function joints are greatly exposed to external violence of all kinds, and in certain constitutions such violence is often followed by very disastrous results. Slight contusions, twists, and sprains, rarely do mischief, but very little will, in some habits, induce action which may be vastly injurious. It is remarkable, however, that joints will often bear with impunity a great amount of violence. It is not customary to reckon the damage of tissues in a simple luxation, displacement being the main feature in such a case, but in most other localities and tissues a similar amount of contusion and laceration would probably cause great distress.

It seems unnecessary here to say anything regarding the simpler forms of injuries of joints, and, as much will be found in after pages regarding luxations and other wounds, there is no need for discussing such topics in this chapter. Perhaps it is worthy of remark, that even the most extensive wounds, involving ruptures and lacerations of tissues, in and around joints, such as occur in luxations, go on most satisfactorily if they are not exposed to the air. This is a fact with which most surgeons are familiar; luxation, in common language, is a simple wound, but should it happen that the parts have once been exposed, or possibly that the air cannot be excluded—conditions constituting the compound luxation, then the progress of the cure may not be so satisfactory; violent inflammation, suppuration, and other evils may arise, and the joint is likely to be lost. So great is the probability of this, and risk at the same time, if the joint be a large one, to limb and life, that the question of amputation may be fairly discussed. In general the leaning is to the practice which may save the limb. But
DISEASES OF JOINTS.

there are other kinds of wounds of joints than luxations. An opening may be made from without, and the gap in the synovial membrane may be large or small. It should not be considered in such cases that the danger of the wound is in proportion to its size. A very slight puncture into a joint may end more unhappily than a large opening. But various circumstances which the surgeon cannot fully appreciate, may influence the effects of such wounds, and assuredly, however trivial the opening may be, it is of the utmost consequence to give the part absolute rest, and to avert by all means in our power the occurrence of undue inflammation. In large openings into joints, such as sabre wounds, accidents in the mowing or reaping field, there seems such inevitable chance of destructive inflammation, that amputation is often thought of in these cases, too, although here also the decision may usually be to spare the limb. Many instances have been recorded where the knee-joint has been extensively laid open by a cutting instrument, including separation of a portion of articular surface and bone, yet the most satisfactory results have followed proper dressing of the wound.

A dislocation and a fracture, leading into a joint, combined, have usually been sufficient to induce immediate amputation, and such a practice has generally been deemed inevitable, where the injuries have been compound; but even here the modern surgeon will pause, especially in civil practice, and when all the appliances for good and successful surgery are at command. In some instances, if the destruction seemed such as to necessitate removal of the damaged parts, he would perform excision, and in either case, if great evil should arise, he would still feel that he had another chance for the patient at his command by amputation. In certain cases there need not be a doubt that immediate or primary amputation should be resorted to, yet as I get older, and thereby further experienced, I am more and more impressed with the idea that the practice of the civil surgeon has been too frequently regulated on the data of the emergencies of the battle-field and camp. But more will be found on such subjects in other sections of the volume.

A moderate amount of inflammation seems to produce little or no ultimate mischief in a joint, as is well illustrated in the case of fracture of the patella. Whatever evil may remain after this injury will be more from the condition of the fragments and mechanical defects, than from any inflammation which may have followed the injury. But often an inflammation, trivial to all appearance at first, may gradually lead to great evil, or possibly a sudden and severe inflammation may be at once developed, to the imminent hazard of joint, limb, or life. In the earlier stages of such afflictions, there will be no question as to what should be done. Every means should be taken to subdue the disease, and thus avert its evil consequences. But frequently, notwithstanding all that may be tried, some of them will arise, and suppuration is perhaps the first or most to be dreaded. There may be a time in many such cases when a difficulty will arise as to the character of the effused fluid. It may be only sero-synovial, in which case it may do no harm,
and need not be interfered with; but it may be pus, in which event it
would probably be very important to give it a free and early vent.
The greater violence of the pain, the œdema of the parts affected, the
previous occurrence of shivering, the additional amount of swelling,
the redness of the surface, and the extreme tenderness to touch, will
all give pretty sure indication of suppuration—in which event the
question of opening the abscess will arise. Generally there has been
much hesitation on the part of the surgeon in taking this step. When
pus is in a joint it may be admitted that the part is in imminent
hazard, and I believe its continued presence is fraught with greater
danger than that which would follow an opening into the joint or
abscess. In my opinion an opening should be made, and in such a
position as to let the matter readily away, both at the time and
afterwards.

In such cases much care should be taken to keep the joint quiet, and
in a position most favourable to the future utility of the limb. The
use of chloroform may be of much service in some of these cases, by
permitting the surgeon to place the limb in a satisfactory position
whilst the patient is under its influence. A certain amount of stiff-
ness, probably a completely rigid state, may remain after the disease
has run its course, and much distortion, as well as subsequent incon-
venience, may be obviated by due attention to the important point of
attitude or position. But, notwithstanding all the care and skill which
may be devoted to the case, some formidable evils may arise, and when
suppuration is present there is a great risk, if not probability, of
ulceration taking place. Ulceration may commence on the surface
of the bone first, so as to separate the cartilage, but more frequently
it first attacks the cartilage, and then extends to the osseous surface.
The extent of disappearance of cartilage or ulceration of bone, will
usually depend upon the violence of the disease or its duration. In
some instances patches only of the cartilage here and there are
removed, and corresponding surfaces of bone are exposed, while in
certain cases a kind of burrowing action will have occurred so as to
loosen the cartilage at various points. Usually in such instances, if the
cartilaginous surface has been extensively removed, the ends of the
bones may be felt bare, by means of a probe introduced through any
external opening which may be present, or possibly, by the grating
of the surfaces against each other when the joint is accidentally moved.
To this condition the term caries is generally applied, but it is that
kind of caries which often gets well, and such as has been referred to
in the chapter on Diseases of Bones, as ulceration of bone in contra-
distinction to the true caries. The latter form of disease, which is also
referred to in the same chapter, is often found on articular ends of
bones, and it is in these cases generally that caries of a joint is
incurable, or gets well only after protracted suffering, and probably
separation of particles, or more considerable portions of bone.

Ulceration or caries of the articular ends of bones may, and often
does, take place, without the evident indications of violent inflamma-
tion above described. Indeed, a most formidable kind of ulceration
DISEASES OF JOINTS.

177

is often met with, in which the external characteristics are mostly wanting: there is neither redness nor swelling, at least the latter is to a very trifling extent, but there is deep-seated gnawing pain, especially at night, which greatly harasses the patient's constitution, and often leads to the worst results. This form of disease affects both articular cartilage and bone much as the other does. It is of chronic character, and may be months or even years in running its course. In the acute forms I have supposed matter to be present, but I believe ulceration in such cases may be present without suppuration, and at any rate in many, if not in most, of the chronic cases, when the external characters of the joint are so little changed as above noted, it is difficult, perhaps impossible, to detect the presence of pus. Nevertheless there may be most extensive loss of structure; all cartilage may have gone, and the ends of the bones may even become altered in shape. Such conditions are familiar in the extremities, and I believe must frequently be the state in disease of the spine, even where much angular distortion occurs. This is a condition of joints which, in as far as I know, has not yet been clearly explained. Can there be suppuration in a joint without ulceration or caries? I should say, yes! Can there be caries in a joint without suppuration? I should say, no! Can there be ulceration in a joint without suppuration? I should say, yes! and I am of opinion that ulceration, in which there may be grating of surfaces, is often confounded with caries (or true caries, as I have named it elsewhere), and hence the uncertainty and variety of opinion as to the curability of what is called caries of a joint. In my view, ulceration in a joint frequently gets well, and that often speedily, although probably at the expense of rigidity or even ankylosis, but that true caries rarely does, except after the lapse of much time, and possibly the separation of particles or considerable portions of the affected bone. There are certain instances of the latter kind, where the reticulated affected structure lies bathed in thin purulent matter, in which the bone has no more chance of being restored to healthy vitality, than in the instances where necrosis is said to be present. In fact, this form of caries, as it is generally called, would in my opinion be more appropriately called necrosis—an example where separation had not taken place between the dead and the living parts of osseous tissue. This state of bone is often present in the ends contiguous to protracted disease of a joint, as at the knee or elbow, and frequently there is a sort of cavity within the bone, with a large or small opening on the surface, which cavity is lined with reticulated bone, and possibly has a considerable portion in a like condition, filling up a large part of the cavity, and attached by a comparatively small neck to the main portion of the bone. Such a case is probably incurable without the evulsion of the bit of bone and reticulated surface alluded to. An idea commonly prevails that when a bone is bare, it is carious, but this I believe to be an error; at all events, the healing process often takes place when such has been the case.

Erosion, ulceration, or caries of the articular surfaces is a serious complication in instances of inflammation. It may be doubted if such
conditions are ever present on one large surface, without the others opposed to it being also affected. Most assuredly such is usually the case; but while the articular surface of one bone may be extensively affected, that opposed to it may be only partially so, and there seems no anatomical or physiological reason why, because the articular end of the tibia, for example, being affected with such diseases, the opposing end of the femur should participate in the mischief. Supposing that the primary inflammation has its origin in the synovial membrane, then it may spread by continuity to both articular surfaces; but as inflammation may be first developed in the end of a bone, its evil consequences may be limited to that locality. If the disease arises here, it has to travel a considerable way, till it can by continuity reach the other bone, and it may be questioned if mere contiguity can have any evil effect. When that condition of a joint occurs in which the articular surfaces are affected, as above indicated, there is always a state more or less analogous in the synovial membrane,—ulceration, softening, thickening, and alteration of fibrous tissues, external to this membrane. The whole parts are in such condition, that a question may very naturally be raised as to the probability of a recurrence to healthy, if not normal action. That a recovery, though with a stiff joint, does happen frequently, is beyond doubt, but in many instances there is much risk to the system, and it may well be doubted if the surgeon is justified in incurring such risk. Often in the progress of disease of a large joint, the last stage of hectic approaches, and the safety of the patient seems beyond the surgeon's power, unless the source of irritation be removed. In such cases issues, secons, the moxa or actual cautery, seem the chief local restoratives, but, as has already been stated elsewhere, with reference to caries, I have great doubts if these are of much service in the latter stages of the diseases now under consideration. In former years, if the above, and all constitutional remedies seemed to fail, the prevailing, if not the only expedient for permanent relief, was the amputation of the limb. I would fain say that at the present time the prevailing expedient is the local excision or resection of the diseased parts. Certain members are not worth preserving at the cost of excision of a joint, and in certain joints the propriety of such an operation is very questionable; but as a general rule this proceeding may almost be called the practice, for in regard to excision as a curative agent there can be no doubt. But in some instances it seems useless to preserve a part, which might in reality be saved by such a method, and amputation of the member above the diseased joint is the preferable plan. Much, however, on which I myself place considerable value in regard to this subject, will be found in subsequent parts of the volume, and with this general expression of my views, I leave it for the present.

In the more chronic forms of disease of joints, there is time to consider what remedies may be best used; and even to test the efficacy of such as may seem most likely to do good. In that form of chronic or subacute inflammation of synovial membrane, which is accompanied with considerable effusion of sero-synovial fluid into the joint, probably
constitutional treatment, conjoined with rest and slight pressure, will bring about a satisfactory result. Some gentle external stimulation may be found advantageous. It has been proposed by some continental surgeons, to treat such cases, much as a hydrocele is now treated by many, with tincture of iodine; viz., that a puncture should be made, to let the fluid escape, and that a solution of the tincture should be injected into the joint. I am not aware that any one in this country has had personal experience in such practice, and for my own part, besides having a great aversion to such a proceeding, I have never seen an instance in which I could have deemed this practice justifiable. Such conditions invariably get well, unless, indeed, there be a greatly altered state of the synovial membrane, in which case effusion is probably not the principal feature of the disease.

But there are other chronic affections of joints more serious than the above. Some of these will be particularly referred to afterwards, and for general illustration I may now allude to the various conditions which constitute the state familiarly known as "white swelling." This term is in very general use, and is occasionally applied in some of the cases above described. Probably, as the words imply, it should be limited to cases where there is conspicuous swelling, and that particular white glistening appearance of the skin so common in the ankle, knee, wrist, or elbow. Probably it may answer all useful purposes to have it understood that "white swelling" implies a very formidable disease of a joint. I am disposed to think that the most obvious characteristic of such a condition is in the substance of the synovial membrane.

It is a common thing for the commencement of a serious disease of a joint to show itself in a way which rarely excites particular notice or anxiety. The elbow and knee give the best examples for general illustration. In the elbow, perhaps, the first thing which may attract attention will be a fulness a little above and on each side of the olecranon process, and inability to stretch the arm to the full extent. Before this, a little pain may have been felt, and probably the arm may not have been used so freely as the other. The arm and forearm will be somewhat thinner than on the other side. If such a case goes on badly the swellings will increase, and, on all sides, the joint will appear enlarged, the arm will be kept slightly bent, and there will be more pain than formerly. Such changes may be months or years in taking place. Perhaps now, and without any perceptible cause, a sudden and distinct inflammation begins in one part of the swelling, and thus, or possibly by a less acute and less painful action, an abscess is formed which threatens to burst into the joint if not opened externally. As the matter accumulates, the swelling throughout increases, the pain is more severe, and there is every indication of the disease taking on a more alarming aspect. At this time I have no doubt that the proper course is to open the abscess. If this be done, or even in the event of the abscess bursting externally, there will be great alleviation of the alarming symptoms, and especially of the pain. Hopes will now be entertained by the patient, or the friends, that the
worse is over. In some few instances such may really be the case, but in the generality, some fresh inflammation and suppuration will ensue, and long and much anxiety will again be excited. In the interval there will have been more or less pain and discharge, although possibly the latter may have dried up. By successive attacks of this kind, the patient's health is much impaired, and, ultimately, if there is no appearance of amendment, the question arises as to what more can be done beyond the means already employed. It is very possible that at this time if a probe be passed into any external opening,—and the successive abscesses may have left several,—the contiguous bone may be felt bare, and possibly, too, there may be clear proof from its course that it has passed into the joint. In all likelihood, towards the latter stages of the disease the patient may have complained of gnawing pain in the joint, as in the example of ulceration in the cartilages referred to in a preceding page. If the ends of the bones are pressed against each other in the early stages of the disease, little, if any, pain will be induced by the movement, but in the latter stages, the slightest pressure of articular surfaces towards each other will induce exquisite suffering. This puts the question as to the cartilages being affected beyond doubt, and thus, during these successive developments of new features, the disease comes to assume an aspect more and more alarming. Ulceration, in all probability true caries, is now added to the primary affection of the synovial membrane, and the three combined—for, in my opinion, there may be ulceration and caries, in conjunction with serious disease of the synovial membrane—may go far to exclude a hope of cure without excision or amputation. Much skill and judgment may be displayed in the decision as to what may be best under the circumstances. The state of the patient's health should go far to decide this question. If it keep up against such continued irritation, there is no urgent call for active interference; it is often a matter of astonishment to witness the favourable issue of some of these cases in the progress of time. It has fallen to my lot to see many instances of joints condemned to excision or amputation, getting well under time. In such cases the friends have usually refused to follow the surgeon's advice. But these cases must be admitted as exceptions to the general rule, and while they may lead us to hope in some instances, they ought not to have great influence on our judgment as to the necessity for an operation when the patient has already had protracted suffering, and may now be threatened with further and more serious inroads upon his health.

In accordance with views already expressed in this chapter, I am disposed to say that excision should be the practice when an operation is decided on; but, as much more will be stated on this important subject in future pages, I shall not dwell on it here. I may allude to the observations on excision at the elbow, shoulder, knee, and hip, as containing more lengthened details of my views and practice in otherwise incurable diseases in these localities.

If excision or amputation be performed in such examples of diseases of joints as have been sketched above, it will be found that the
DISEASES OF JOINTS.

synovial membrane is most involved. Different from the first form of serious disease described as requiring one or other of these operations, the membrane in question will be found converted into a fibro-gelatinous mass, more or less distinct, according to the looseness naturally of this membrane, and also according to the age of the disease. This condition has been particularly referred to by Sir Benjamin Brodie, in his valuable work upon "Diseases of Joints." The gelatinous alteration, or "degeneration," as it has been called, may possibly be less conspicuous at a late period of the disease than at a prior date. It seems to be entirely on or in the loose external parts of the membrane. If there has been much suppuration this state is not so remarkable; and in those instances where abscesses have ultimately healed, there is none of this adventitious tissue in the cicatrices. It seems to me of importance to distinguish between this kind of swelling and that which may be deemed the result of ordinary inflammation. Much of the swelling in severe cases of disease of joints depends more upon deposits of serum, lymph, and pus, than on this gelatinous degeneration. There is, however, this great feature of difference between the two conditions: viz., that as great swelling is in general the result of some conspicuous cause of irritation,—in such cases caries or necrosis being in all probability present,—as soon as that cause is removed — as by excision — the swelling subsides; whereas, if the swelling is chiefly from this condition of the membrane, it will not subside so readily, and, indeed, it may be considered of much importance in such cases to remove the whole of this tissue, as it assumes a comparatively healthy state very slowly.

Regarding the treatment of such cases as have been last referred to, there is much diversity of practice. In the earlier stages there seems so little amiss, and there is so little complaint from the patient, that there appears scarcely occasion to interfere. But even now the treatment applicable in more distinct inflammation may prove of service. Leeches and fomentations may perhaps arrest some alarming indications. Such measures may be resorted to frequently. Blisters may be found of much value in the intervals, and these, also, may be repeated as often as shall seem desirable. Possibly some other form of counter-irritation may be preferred. Compound tincture of iodine, in its saturated form, often now called "iodine paint," or iodine liniment, may be used with advantage, both as a counter-irritant, and in the faith that the iodine has specific virtues in inducing absorption. Setons, caustics, moxa, and actual cauterity, may all be tried in succession, but, whatever may be done, rest must form an important feature in the treatment. There need be no doubt that this important local mode of treatment is of greater service, generally speaking, than any other single measure. In the earlier stages disease may be wholly arrested by it, and it should not at any period be deemed a secondary measure. I have no doubt that it constituted the most essential part of the practice of the Scotts—father and son—and had more influence than the ingredients of the plasters with which joints were so carefully enveloped. Rest must be given in various ways according to circum-
stances. Sometimes it will be best to keep the patient in bed, and even here additional means for quietude must be resorted to. Bandages, common or elastic, straps, and splints, are all in ordinary use, and whilst these are applied, much care should be bestowed in keeping the joint in such a position as might be most desirable, should there be a prospect of future stiffness. In all such cases, as a matter of course, the general health must be looked to, and, as it is often of essential service that the patient should have the benefit of the open air and change of locality, such splints may be used as shall prove least cumbersome. Those of leather, gutta percha, prepared felt, bandages with starch, dextrine, glue, or plaster of Paris, are in common use for such purposes. Various plasters, which produce gentle stimulation of the surface, may be used in conjunction with the splints, and the slight pressure of the bandages, which may be used to keep the plaster and splints in their proper positions, may be of service in causing absorption of such effusions as are the effects of inflammatory action.

For notices of various other affections of joints, I must refer to subsequent pages. This chapter is intended to convey only such general principles as I deem requisite in accordance with the arrangements on which the work has been constructed.

CHAPTER XXV.

AMPUTATION. DRESSING OF STUMPS.

The term amputation is generally used with reference to the separation of a portion or the whole of an extremity by a surgical operation, although it is also often used to indicate the removal of a tumour, such as a diseased mamma or testicle, or other morbid growth. It is in the former sense that I shall allude to it in the present chapter. Few operations have attracted more attention than this; and although it is a fashion with some to speak of it as the opprobrium of surgery, it is impossible to anticipate a time when such a proceeding shall be entirely dispensed with. Modern surgery has done much to obviate the necessity for the operation in cases of disease, and unquestionably many damaged limbs which were, in former times, deemed beyond remedy, are now successfully treated otherwise; but the surgeon cannot be held responsible for the irregularities of nature, nor can he avert those injuries which so frequently lead to this lamentable necessity.

It is almost needless to say that amputation should be performed only under circumstances when no other means will avail. The difficulties of determining these circumstances are often very great, and sufficient to perplex even the most experienced practitioner. The rules set forth by writers on the subject usually refer to such injuries and diseases of parts, that the youngest in the profession may at once
see their force and truth; but the cases which admit of doubt can scarcely be detailed beforehand, for each has its own particular features, such as no forethought can anticipate. The period when an operation should be performed may be more positively defined than the circumstances last alluded to; and, although there is much uncertainty even here, I imagine that some observations on the subject will serve to make this chapter more complete.

The question has reference entirely to cases of injury, and the constitution as well as the wound may be in different conditions in an example of the kind. At first the party injured will probably be in his ordinary state of health—saving the damage which has been done—and the wound will be much as it has been left after the external violence; during the first twenty-four or thirty-six hours, action of an inflammatory character will begin in and around the damaged tissues, and in this time, too, there will be a certain amount of constitutional excitement or sympathetic fever; the local and general affections will become more conspicuous in a few days; suppuration more or less profuse will ensue, and possibly sloughing may occur; gradually the body will become emaciated, the fever will alter its character, and probably assume the indications of hectic; when, if amputation is to be done at all, the last period for its performance has arrived.

There are three dates, then, which surgeons speak of with reference to amputation after injuries: and if the operation be done any time during the first stage above alluded to, it is termed "primary;" if the second, it is called "intermediary;" and in the last stage, it is said to be "secondary." The first and last of these terms have been most commonly in use, but the intermediary date, as has been ably pointed out by Sir Rutherford Aleoek, is fully worthy of distinction in such a very interesting question.

It would occupy too much space for the purposes of this work to enter at length upon the discussion of the question as to the proper period for amputation; neither is it necessary to do so, as the details are fully given by many authors. The modern practitioner has been guided in his proceedings chiefly by the authority of military surgeons, the majority of whom have decided in favour of primary amputation. Mr. Guthrie has been one of the principal advocates of this doctrine, and the corroborative evidence of Larrey, Hennau, and others, has been further strengthened by the testimony of Mr. Hutchinson and Sir Stephen Hammick among naval practitioners. But, as has been justly pointed out by Sir Rutherford Aleoek and Sir George Ballingall, the circumstances of patients in military practice are not altogether parallel with those coming under the civil surgeon; and in the present day the feeling seems to gain ground that distinctions should be drawn between the two classes, as much on account of the difference of constitution of soldiers, as the peculiarity of situation in which the different patients may be placed. My friend and former pupil, the late Dr. Henry Reid, of Manchester, devoted particular attention to this question, having made it the subject of a thesis, for which the
Amputation.

Graduation medal for 1843 was awarded at the Edinburgh University. Dr. Reid obligingly favoured me with an inspection of many of his tables, and with the results deduced from his investigations. The balance is greatly in favour of the delayed or secondary proceeding, and the intermediary is shown to be somewhat more fatal than the primary. As the practitioner in civil life has often greater facilities for treating his patients in accordance with the dictates of professional skill than is afforded in time of war, it will be obvious, from the statement above made in favour of secondary operations, that in instances admitting of a doubt as to whether amputation be absolutely requisite, there is great encouragement for delay—the limb should have the favour of the doubt; and should it unfortunately appear that the part must be sacrificed, the patient has still a better chance of recovering from the operation than if it had been done at first.

When I look back upon my own personal experience in such cases, I cannot but declare my inclination for delay; yet, under any circumstances, it is quite evident that much must be left to the discretion of the surgeon as to the proper course to be pursued. It is a maxim almost invariably applicable, never to amputate while a patient is in a state of shock; and though it may occasionally be deviated from even with success, there need be no doubt as to the wisdom of the delay. Some persons do not suffer at all from this condition, and in such instances, if a primary operation is determined on, I agree with Mr. Hutchinson that the sooner it is done the better. Yet it is well to bear in mind that possibly there may be some other cause for collapse besides what may be visible, and that internal injuries may have been inflicted which would of themselves be sufficient to destroy life; for in such cases an operation would be worse than useless.

It will be afterwards found, that, in describing the mode of amputating in different parts of the extremities, I have almost invariably recommended the flap operation, as it is called; that is, by preserving the principal part of the future covering of the exposed bone or bones, from one or two sides of the limb, by the single flap or the double, according to circumstances. Since 1679, when Lowdham first proposed this operation, there has been great controversy as to its merits, and those of the mode by circular incisions. Previous to the last forty years, although the flap operation may be said to be entirely British in its origin, the circular method seems, with few exceptions, to have been universally followed by surgeons of this country. The proceeding by flaps was again introduced, especially among those educated in Edinburgh within the above named period. The influence and example of Messrs. Liston, Lizars, and Syme, must have induced thousands to follow this plan. Sir George Ballingall also invariably performed the flap operation during the time he officiated as acting surgeon in the Royal Infirmary, although it appears, from his valuable work on Military Surgery, that he does not assent to all the advantages that have been claimed for this mode, nor acquiesce in the abuse which has been heaped on the circular incisions. Like other pupils of the school, I myself imitated the practice of my seniors; and I believe I
AMPUTATION.

185

am correct in stating that, during a period of twelve years, the circular operation was never performed in the Edinburgh Hospital until it was again done by myself, during the latter part of my service in that institution. It appears from the statistical tables of the establishment, drawn up by my respected friend, the late Professor Reid, of St. Andrew's, that in two years (from July 1839 to July 1841), sixty-nine amputations on the extremities were performed in the Royal Infirmary of Edinburgh, and it will therefore not be unreasonable to suppose, that upwards of four hundred similar operations were performed in the above twelve years. When the operations in private, during the same period, by the flap method also, are added to this number, it may readily be perceived how widely the example must have spread. Having, with few exceptions, witnessed all those done in public, and seen and been engaged in a reasonable proportion of private cases, it could scarcely be otherwise than that I should, in my own practice, follow the flap incisions; especially when I contrasted them with the occasional circular operations which, from time to time, I witnessed elsewhere, and when, in addition, I compared the stumps made by the two methods, and consequently by different practitioners.

I feel that my personal experience with the circular operation has not been such as to entitle me to give an impartial opinion regarding the two modes. I must say, however, that in so far as results are concerned, I place far less importance on some of the distinctions between these operations, than has been done by certain authorities on the subject.

If rapidity of execution is to be taken as the test of superiority, then I imagine that the flap operation must be allowed the preference; but in the hands of a good surgeon, the difference of time required for the efficient performance of either, seems to me of so little consequence, that such a calculation should not be taken into account. I once heard a surgeon of very considerable experience argue, that if the cutting part of an amputation were well done in twenty or thirty minutes, the performance was as creditable to the operator as if it were done in one, three, or five; but there must be few who entertain such a doctrine: had he pleaded for a few seconds, or minutes at most, no one could have deemed him unreasonable. It has been stated by Rous, in the account of his journey to London in 1814, that he witnessed, in one of the London Hospitals, a circular amputation, in which "nearly twenty minutes had been employed in only the separation of the limb." I feel assured that he could have seen nothing of the kind during his brief visits in 1841 or 1851. Such a mode of proceeding ought not to be taken into account in discussing the question of rapidity in the two operations; for I imagine that the same individual who thus ingeniously expended "nearly twenty minutes" in using the knife and saw, would also contrive, in some way or other, to occupy a similar period in performing the flap operation. I cannot but think that the same hand which rapidly and safely completes the flap incision, would, with almost equal facility, if equally well trained, accomplish the circular. On this point I can speak from my own trials
of the circular, which I have accomplished, in the manner described hereafter, in nearly the same space of time that I should have taken for the flap operation in the same limbs, although, from the want of a like amount of practice as with the flap, I have felt more awkward in the accomplishment of my design, and perhaps, also, from certain circumstances to be referred to afterwards, a little more difficulty. A surgeon of the present day who takes more than from thirty seconds to three minutes (excepting under peculiar circumstances) for the performance of an amputation, whether flap or circular, ought not, in my opinion, to be taken as an authority on the subject.

The comparative extent of cut surfaces in the respective operations seems to me of trifling import;—a few inches more or less, provided always that a good stump is left, will never, in my opinion, determine the issue of an amputation. The bleeding during such a proceeding is greatly, perhaps entirely, under the control of the surgeon. If he cuts in parts where the vessels have been long in a state of chronic enlargement, he may be certain that more will require ligatures than under other circumstances; and in such a case, also, if the tourniquet is not used, the loss of blood must of necessity be greater, and this will happen in either mode of operation. It has been asserted by Sir George Ballingall, and others, that the vessels retract more completely in the circular operation; yet in a valuable essay by Dr. Machardy, on the comparative merits of the two modes, it was stated by that gentleman, who witnessed a circular operation done by myself, that the dripping of the blood on the floor seemed like the noise of rain falling on a cupola. In the case alluded to, there certainly was copious hemorrhage, and numerous ligatures were required; but in reference to the above statement I may here remark that the only instance (exclusive of cases of gangrene) in which I have seen a single ligature alone required in the thigh, was a circular operation. It must be admitted, however, that if the bleeding is more copious in the flaps, it is easier to get at the deep part of the wound, than in the hollow cone of the circular incision. When "nine" ligatures have already been applied to the flaps of a stump, it may be considered a serious matter if "eleven" more are required; but I cannot suppose the necessity here (for such a case is referred to by Sir George Ballingall) was occasioned by the mode of incision: had a circular wound been made in the same textures, I have no doubt that the bleeding would also have been troublesome; and even admitting that a few ligatures less might have been required than in the other method, I fancy that the result of the operation would not have been influenced thereby. Two or three ligatures, more or less, can never make any material difference in the results of an amputation.

It has been asserted, in most controversies on this question, that in the circular operation the skin alone is left to cover the end of the bone, whereas in the flap method there is a cushion of muscular fibres preserved, which afterwards protects the part, and lessens the chance of injury from pressure. The nature of the covering, however, depends greatly on the manner in which the operation is performed.
In the circular, if the skin is freely dissected upwards before the other soft parts are divided, the end of the stump will be formed only by this texture; but if the incisions are so managed as to leave a sloping surface from the edge of the divided bone to that of the skin, and if a sufficiency of soft parts be left, the covering of the bone may thus be as thick (as muscular) as by the flap operation. In the leg, one side of the stump, when formed by the circular proceeding, must always be formed of skin only; but in the thigh, arm, and upper part of the fore-arm, it is quite possible to preserve the parts in the manner above referred to. It is worthy of remark, that the muscularity of the calf of the leg has been made an objection to the flap operation in this situation, and that pains have been taken by some of the greatest advocates for this proceeding,—those who insist on the necessity for a thick covering,—to make the incisions in such a manner as to preserve the skin only. Mr. Liston recommended that in this situation “two semilunar flaps had better be made, one from the anterior aspect of the limb, the other from the posterior, the muscles being cut short in the ham.” In very muscular subjects, the large posterior flap which is usually made here, is almost certain to project considerably beyond the skin; I have noticed a similar thing with the deltoid muscle after amputation at the shoulder joint: the occurrence retards the cure; but in the course of some additional time, perhaps a month or a few weeks more, the stump differs little from one where no such protrusion has ever happened. In either of these cases, and whether the operation has been by flap or by circular wound, the stumps are at last so much alike in certain parts of the body, that it is occasionally difficult, after the lapse of years, to say whether an amputation has been by one mode or the other; at all events, when such distinction can be drawn from the shape of the cicatrices, it is evident that the end of the bone is covered by much the same thickness of soft parts in one instance as in the other. If there has been a full fleshy stump shortly after the operation, all muscular fibre has at last disappeared, and the skin, with a substance resembling condensed cellular texture, alone covers the bone. This substance, undoubtedly, gives great protection to the end of the bone, and its presence is absolutely necessary, I should almost say, to constitute what may be deemed a good and useful stump; therefore, whether the circular or flap incisions are resorted to, I would always endeavour to preserve more than the skin for a covering. The rugged and uneven surfaces which are usually made by the circular incision, form with some parties an objection to this operation also, as they may possibly not come accurately into apposition, and thus union by the first intention may be prevented; but it is so difficult to calculate on the contraction of muscles in such operations, that I doubt if any accurate data can be collected on these matters. Non-union, suppuration, and granulation, may happen from one operation as well as the other; and whether union by the first intention has been obtained or not, I believe that most surgeons of experience will join me in opinion, that more trouble will result from some little point of the wound where union has not occurred, than from any want of
it resulting from the irregularity of surface above referred to. I feel bound to state, that I have seen adhesion by the first intention follow as perfectly after the circular operation as after the flap; and, in addition, have observed as good stumps from the one as the other.

It is impossible to argue that non-union, suppuration, exposure of end of bone, exfoliation, tumours on nerves, and so forth, have not followed the circular operation,—all these evils must be admitted; but the same results have occurred from the method by flap. It is, indeed, difficult to imagine why the circular incisions should cause all the above troublesome results, whilst the flap method should avoid them: for my part, I shall not feel convinced on the subject, until I see that such is really the case,—until I witness a certain number of amputations by these two methods, done by the same surgeon, or by two who are equally competent, and find all the evils on one side, and the advantages on the other. It seems to me that some such proof as this is still wanting for the surgeons of the present day. It is not to be overlooked that some of the most distinguished in the profession have almost invariably performed the circular operation, and surely all the stumps formed by these gentlemen were not so bad as the advocates for the flap would lead us to suppose.

If a circular operation is improperly performed, the whole catalogue of evils may result; but the same may ensue from the method by flap. I do not here speak from conjecture, for I have seen as thorough exposure of bone after a flap operation as after a circular. If, in the circular, the incisions are too directly down to the bone, and no adequate provision has been made for covering its cut end, there is no calculating what may follow: if by the other operation the flaps are not well made,—being too short, and selected from improper parts of the limb,—the same evils may ensue. In short, in so far as my experience goes, the evils resulting from one proceeding may be as great as from the other, and must be the result of a badly performed operation by either.

With these views, then, it may seem strange why I should not have operated almost as frequently by the one method as the other; but the following observations probably tell the cause. Sir George Ballingall, after nearly thirty years' experience in military hospitals, and more than fifteen in civil institutions,—who, as has already been stated, during his period of operating in the Royal Infirmary of Edinburgh, performed the flap operation invariably whilst I had an opportunity of observing,—who may, notwithstanding, be considered less prejudiced than some other authorities, thus writes: "The flap operation is a seductive one, and I can speak from my own experience when I say, that it is an operation which one is unwilling to relinquish after having once experienced the comparative facility of its execution." The last part of this sentence implies, in my estimation, a most important distinction between the two proceedings, and has probably had the greatest influence in determining my own line of practice; but here let it be remarked, that I speak with reference to the performance of the respective operations, not their results.

Any one who has had opportunities of contrasting the two modes,
AMPUTATION.

189

must have been struck with the apparent advantages in the execution of the one over the other; the facility of selecting a flap from any convenient side, the comparative ease with which it may be cut, the greater certainty of preserving a sufficiency of soft parts, the readiness with which the bone can be exposed for the application of the saw, are all, in my opinion, important advantages in favour of the flap operation. In the thigh, for example, it is easier to transfix, and cut a flap on each side, three or four inches long, than to preserve a covering, of similar length, by circular incisions; in the latter, I imagine that the soft parts cannot be so easily drawn up; and if considerable force is not used in this stage of the proceeding, even a practised surgeon may find that the bone, when cut, is too much on a level with the rest of the surface. In the flap operation the slightest force,—little more than the mere lifting of the flaps,—will suffice for retraction.

The limited extent of this work forbids me to enter further on these matters at the present time. I trust it may be considered that I have dealt fairly with the circular operation: I deem it inferior to the other, as regards execution, but I think that it remains to be proved (not by assertion, but by actual experience in the manner alluded to in a former page), whether, when equal skill and pains are bestowed, and the same mode of dressing is applied to each, the results are so very different, as some modern authorities would lead us to believe.

The flap operation seems by universal consent to be superior to the circular when amputation is required at an articulation, although, as will afterwards be found, it has been proposed to amputate at the hip-joint even by the circular method.

The individual flap operations will be described in future pages; but to save repetition, I shall here introduce a description of a circular amputation, which may enable either a student or practitioner to apply the method to any part of the body he may think fit. The knife, saw, and other appurtenances, may be the same as for a flap operation. The kind of knife I have used in my own practice is represented in the next figure, and it seems to me as efficient for the purpose as the clumsy instruments generally used by those who always practise the circular incision. In the flap operation, the fingers of an assistant are sufficient for the purpose of retracting flaps; but here some additional means are almost indispensable. A piece of stout linen cloth, four or six inches in breadth, and about eighteen in length, split lengthwise about ten or twelve inches, into two or three ends, in accordance with the number of bones in the seat of operation, will answer all the purposes of the leather or metal retractors used in former times: three ends being required for two bones, as in the fore-arm or leg,—two being sufficient for the arm or thigh.

When all preliminary arrangements such as are required for the flap operation are completed, an assistant should grasp the limb with both hands, and draw the skin upwards, both for the purpose of preserving a portion of it, and to render the surface tense,—or the surgeon may do so with his left hand, whilst with the right he places the knife in the position represented in the accompanying drawing
(fig. 78): to do so, he requires to stoop, and bend the hand well backwards. Holding the instrument lightly between the fingers, as here exhibited, or (if he prefers) grasping it firmly in the closed palm, he sinks the edge through the skin, draws it deliberately round under the limb, and then over it, gradually changing the bend of the wrist, until the hand is as much bent forwards as it previously was in the opposite direction, and thus completes a circular wound. Whatever be the extent of natural retraction, the integuments should next be drawn upwards by an assistant, encircling the limb with the forefinger and thumb of both hands; and to facilitate the upward movement, the sharp edge of the knife may be applied wherever the attachments seem to require division. Again, the knife should be made to sweep round the limb as in the first part of the operation, being kept close to the surface of the retracted integuments, and passed half an inch or more through aponeurosis, and superficial muscular fibres; now the assistant should place his fingers and thumbs deeper in the wound, and apply more force, so as to retract both skin and the parts last divided; for the third time, the instrument should encircle the limb, so as to divide every texture down to the bone; here the retractor should be put on in such a way as to cover the greater part of the wound, and then drawn forcibly upwards: it may be pulled an inch or more above the part where the knife has first touched the periosteum, when muscular fibres will appear in the centre, still adhering to the bone; these must be divided close up to the cloth, either with another circular sweep, or by applying the point of the knife; if on the application of a little more retractor force, any additional fibres appear, they must also be divided in the same way, and then the saw must be applied at the highest part where the bone is exposed.

A variety of circumstances may influence the extent and facility of retraction; but to preserve a sufficient covering by the operation just described, I consider it always requisite to apply a good deal of force, —certainly much more than is required for the retraction of flaps. Sometimes the fingers alone will suffice, but in general the retractor will be found more efficient.

By the operation as thus described, there will be a sloping surface,
from the edge of the skin up to the bone; the wound will represent a
"conical cavity," as described by Alanson, and, provided the retraction
has been sufficient, a "fleshy" stump will be formed. I do not deem
it at all necessary to place the knife obliquely, nor to use it in the
manner described by the celebrated authority last named. The cut-
ting instrument may, in all the cireular incisions, be held at right
angles with the bone, and the retraction, first with the fingers and then
with the linen band, seems to me to obviate the stumbling-block which
commentators on Alanson's operation have always brought forward
against the plan proposed by him. It is evident that Alanson could
not have applied the saw at the apex of the cone without drawing the
parts upwards; he must have done so, although he does not clearly
state the circumstance; and it is somewhat singular, that even in the
second edition of his work, when he adverts to the misunderstanding
that had arisen about his operation, he should not have pointed out
that the "conical cavity" was not made from hard incompressible
materials, but from those of a soft flexible nature, such as could be
caused by pressure to assume almost any form or shape for the time
being. Perhaps he did not think it requisite to notice such an appa-
rent circumstance; but I cannot divest myself of the idea that some
have supposed, that in order to form the cone, a kind of process is
required, such as might be necessary to make a similar figure in a bit
of wood, or other equally incompressible substance. By the foreible
retraction, the length of the cone is made scarcely appreciable; but as
soon as the pressure is taken off, it becomes apparent.

I am convinced that if the circular incision is made through skin,
muscles, and all, at one and the same sweep, it will scarcely be possi-
ble to cut the bone sufficiently high; if, on the other hand, the
integument be much everted, or actually dissected upwards, as was
described by Sir Charles Bell, and then the muscles be cut right down
to the bone by a second incision, as was recommended by Sharp, I
imagine that there is a great probability of the covering being formed
by skin only; thus giving rise to one of the strongest objections to the
circular operation.

It has often appeared to me, that there has been an objectionable
formality enjoined regarding amputations, which has thrown great
difficulty in the way of the young surgeon, who has as yet been unable
to shape his own course from personal experience. Instead of leading
him to suppose that one, two, or three circular incisions constitute the
only correct operation,—instead of wishing him to imagine that in the
proceedings above described he must limit himself to three, or at most
four, circular sweeps, I should say that he may, if he sees fit, apply the
knife again and again in the same manner, without the alleged rugged
surfaces of the wound, which some have objected to, being apparent.
I shall have occasion afterwards to advert to the needlessness of dog-
matic statements regarding other operations besides amputations, yet
here I cannot help adverting to the folly of setting rules on points
which may with all propriety be left to the option of the acting sur-
geon, such as about standing on one or other side of the limb, applying
the saw, and so forth; I cannot, however, omit alluding to a mode of
teaching, equally objectionable, in my estimation, as that above referred to, which, whilst one good authority inculcates the necessity for the circular mode of operation where two bones are present, another, equally estimable, characterizes the proceeding as being "altogether inadmissible" in such a situation; meanwhile, the student may go from hospital to hospital, and see excellent stumps formed by either mode.

It is difficult to say, on such an occasion as this, what should be the length of the coverings. Measurements by inches may do very well on the dead subject, or other inanimate material, but they are unsafe to trust to on the living body. The muscles and other textures will retract much more in one person than in another, and a limited length of soft parts, which would make an excellent stump in one limb, might leave the bone projecting in another. As a general rule, it is safe practice to leave the covering rather too long, than what might be deemed the exact and proper length; but on these points more will be said hereafter, when the individual operations are considered.

Since the last edition of this work, the mechanical process of amputation has been varied in a manner little expected by those who were educated forty years ago. Instead of the "fleshy" semicircular edged flaps, then so much advocated, the late Mr. Teale, of Leeds, has urged the advantages of rectangular flaps of skin chiefly, and dividing the main vessels and nerves so high that they may not afterwards lie across the stump and be exposed to pressure. Mr. Carden, of Worcester, has also contributed to this subject in reference to amputation at the knee, and of both of these authors—worthy representatives of the modern surgery of Britain—more notice will be taken in future chapters of this volume devoted to the subject of Amputation.

Whether an amputation is done by flap or circular incision, it is almost the invariable practice among British surgeons of the present day to promote union by the first intention; and, for this purpose, as soon as the bleeding has been arrested by the application of ligatures or otherwise, the surfaces of the wound are brought into apposition, and retained thus by means of stitches, straps, and bandages. It is the custom of some to allow several hours to pass, ere the edges or surfaces are finally adjusted; and this is done with the intention of making sure that all bleeding has actually ceased, as also under the conviction that union is not retarded by keeping the surfaces so long from each other. If the edges of such a wound are brought together immediately after the operation, and probably whilst the patient is faint from the shock, there is a chance of some vessel beginning to bleed after he has got warm in bed; and on this account it may be necessary to undo all the dressings. In general, however, if proper care be taken to apply a sufficient number of ligatures at the time of the operation, there will be no further trouble; and I do not hesitate to recommend that, as a common rule, the wound of an amputation should be dressed whilst the patient is on the operating table. I have tried both ways, and have always remarked the additional distress which any interference with the wound, four, six, or eight hours afterwards, has occasioned. In the present day, when chloroform is almost
invariably used, the advantage of a primary dressing can scarcely be disputed.

In a circular operation, when the cut surfaces are laid together, the line of junction may be transverse, vertical, or oblique, at the will or taste of the surgeon. I know of no rule which should regulate this circumstance, and hold it absurd to make a deliberate provision for the after-flow of matter: indeed, a stump may be in so many different positions during the progress of treatment, that what may at one time be the most dependent part, may be the reverse in the course of a few minutes, hours, or days, according to the movements of the patient. In the flap operation, the line of junction can only be as the flaps are formed. In either proceeding, the ends of the ligatures should be brought out at the points nearest the vessels on which they are placed: if there be no great distance between two or three of them, they may be brought out at the same point; but I consider it improper to cause a thread to traverse a large extent of wound. It is often the custom to cast a knot on the ligature round the main artery, so that it may be known when separation takes place.

The dressing of a stump must be conducted on the principles inculcated in previous pages; but it may not be deemed supererogatory if I here give an outline of the course which I would in general recommend. Supposing that immediate union is desired, the main features of treatment and dressing should be to keep the surfaces quiet and in accurate apposition. The latter object I think is best attained by means of stitches, straps, and bandages; the former by proper position of the stump, and such other means, local and constitutional, as may be thought essential to allay irritation.

But, to be more precise, I shall instance an example of a stump in the thigh. Here, after the requisite number of ligatures have been applied, the wound must be carefully cleansed with a wet sponge, and, the surfaces being placed in apposition, six, eight, or ten stitches should be used to keep them together: four, six, or eight strips of adhesive plaster, each about eight inches long, should then be applied in the intervals between the sutures; then a narrow bit of lint, wet or dry, or spread with spermacteal ointment, should be laid along the whole length of the wound; lastly, a roller should be applied, with a very moderate tightness around the limb from the pelvis downwards, and to give additional steadiness, it may be brought several times across the end of the stump. In the course of three, six, or ten days, chiefly according to the presence or absence of discharge, the roller should be cut or undone, the strip of lint taken off, the stitches cut out, the straps removed and fresh ones applied, with lint wet or with ointment, and a clean roller again put round the parts. The dressings must be removed once perhaps every twenty-four hours for the next ten or fifteen days. At this time, probably, all the ligatures may have separated; and now, perhaps, if any part of the wound gapes, or there is any disposition in the flaps to go awry, a little more pressure may be used both with straps and bandages. Any part of the wound which remains open, will in all probability be a healthy granulating surface,
which has a tendency to heal of its own accord. Sometimes stimulating lotions or ointments, such as those used on granulating sores, may be of service. For fifteen or twenty days the patient must be kept in bed, and soon after all the ligatures have separated, when the wound has nearly closed, he may be allowed to get up. In a month or six weeks, provided everything has gone on well, the wound will be completely healed,—no further dressing will be required, unless, perhaps, the daily application of the roller, which I think it well to continue for some considerable time afterwards, both as giving a good support to the newly-formed adhesions, and also as being useful in keeping the stump of a good shape.

Many modifications of the above proceedings will be required, from circumstances which it would be useless, if not impossible, to enumerate here. Much of what may be deemed sound practice must depend on the good sense of the surgeon. The custom of covering the end of a stump with thick dressings is, in my opinion, highly objectionable, and is a relic of old, ignorant, and barbarous surgery, which ought to be done away with entirely; indeed, when the surfaces show no disposition to separate, I do not on all occasions deem it requisite to apply even the somewhat loose bandage above recommended. I have seen a stump of the thigh, by the circular operation too, admirably treated without any covering at all, excepting a narrow slip of lint applied over the stitches; and I may refer to the stump of the leg, afterwards represented in one of the drawings, which was treated for three weeks, with the exception of the first eight-and-forty hours, without any bandage or support whatever. Commonly, however, a bandage will be highly serviceable, more especially towards the latter part of the treatment, when it may be used with great effect in giving the stump a proper shape.

When union by the first intention does not take place, or if this is not expected—as in some instances when it is advisable to stuff the wound with lint to check hemorrhage—the treatment must be such as to encourage suppuration and granulation; and if care be taken, as the latter process is going on, to keep the soft parts properly supported by straps and bandages, the wound may ultimately close so perfectly, that it may be difficult for a stranger to say whether it has healed by immediate union or by granulation.

Most of the casualties likely to follow amputation require no special comment here. Defective union, from whatever cause it may be,—whether from excess of inflammatory action, from an absence of the adhesive process, or from sloughing,—all implying the necessary occurrence of suppuration and granulation ere the wound can close, must be treated on principles already elucidated, though in a brief manner, in preceding pages. Secondary hemorrhage, too, has been discussed, and will occasionally be alluded to again, and such as are not particularly referred to, are usually of a nature requiring no especial notice here, as I imagine that a slight acquaintance with the principles of surgery will enable even the youngest practitioner to treat each case according to the combined dictates of skill and prudence.
PART II.

OF THE SUPERIOR EXTREMITY.

CHAPTER I.

SURGERY OF THE UPPER EXTREMITY.

A general glance at the injuries and surgical diseases of the upper extremity, will form an appropriate introduction to the following chapters on the practical surgery of this part of the body.

Comparatively, the casualties which befall the upper extremities are not so serious as those of a similar kind which happen in the lower limb. The amount of injurious influence on the whole frame is not so great; what, in the lower limb, may necessitate confinement to the house for weeks, need not, in the upper, demand the restriction of a day; and the amount of danger to limb or life may possibly be reckoned in proportion to the extent or bulk of tissue wounded. A severe crushing damage, involving contusion, laceration, fracture, and wound of joints in the hand, is productive of less danger than a similar injury of the foot. But, in different cases, much will depend on the constitution, for one person may recover from a comparatively severe injury of the foot, while another may die of a trivial lesion in the hand. Where evil arises it may depend greatly on the particular part or structure involved in the injury. A question is often discussed as to whether a certain amount of loss in the upper extremity is better or worse than a corresponding loss in the lower extremity. It seems to me scarcely to admit of argument. The loss of a foot is trivial in comparison with the loss of a hand. The latter organ is so superior in utility to man, that there is no comparison as to its relative value. The foot may be said to be merely the servant of the body; the hand, with all its physical utility, is eminently the servant of the mind. The temporary effects on the constitution of the loss of a foot are, doubtless, more severe and hazardous to life than those following amputation of the hand; but, supposing recovery from both, the deprivation of the hand is more severely felt than that of the foot. There may, possibly, be some few exceptions to this general conclusion, but they must be few indeed, and very special.

The upper extremity, from its exposed position, is liable to all kinds of accidents; scalds and burns, sprains, contusions—incised, punctured, poisoned—and other sorts of wounds, are exceedingly common, and
even the more severe cases of fractures and wounds of joints are very frequently met with. The hand, being so much more exposed than any other part, is exceedingly liable to injury, and often the most serious deprivations follow. In civil life, gun-shot injuries, or, perhaps to name them more correctly, lacerations resulting from explosions of gunpowder, are of very common occurrence. Occasionally, by shot from the muzzle of a fowling-piece, but more frequently, in consequence of the bursting of the barrel near the breech, the hand is damaged, and various degrees of injury are the result. Some such cases will be referred to in after pages in this section, and the important point of preserving as large an amount of the hand as possible will be duly insisted upon and illustrated. It has fallen to my lot to be consulted frequently upon the propriety of preserving portions of the hand under such circumstances, and I have much pleasure in bearing testimony to the conservative surgery generally practised in the present day in this respect. In early life, I once saw a deplorable proof to the contrary, which probably had the effect of drawing my attention particularly to this subject. A gentleman, in pursuit of partridges, had his hand lacerated by the bursting of his fowling-piece, and amputation was performed in the fore-arm. An assistant who was present had the blood-vessels of the separated part filled with a common wax injection, and dissection showed that all the main arterics, nerves, and tendons were entire. So far as I could judge, I had never seen an example of more officious and ill-judged surgery. Had the gentleman who displayed his skill with the amputating knife in this case, held more reliance on the powers of nature, or more faith in the resources of surgery in a secondary operation, there was no doubt in my mind that the sufferer from whom this hand was taken would have retained a useful member; for I cannot but think that, however extensive the injury may have appeared on the surface, there was so little damage to the important structures of the hand that a happy result would have followed the treatment of the wound. If this had gone on unsatisfactorily, a secondary amputation could still have been resorted to. From various parts of this volume it may be gathered that I am averse to primary amputation in civil practice where there arises any doubt on the subject; and in this extremity when the proposed amputation involved the whole hand, I should be particularly disposed to act on the rule of delaying amputation to the last. But I may here refer for further observations on such subjects to the chapters on Incisions and Excisions, and on Amputations; and also to those on Dislocations and Fractures, which will comprise the rules of surgery as to the more important wounds and injuries of joints and bones.

There are few diseases of an inflammatory character which can be said to be peculiar to the upper extremity. Inflammation and its consequences are much the same here as in other localities. Contrasting the hand with the foot, many more instances of inflammation are met with in the upper extremity than in the lower. Even allowing for all the annoyances and mischief from tight or ill-fitting shoes, corns, and bunions, the hand is more frequently the seat of inflammatory
mischief. Such a case as a poisoned wound in the foot is never met with in civilized life, but in the hand it is one of the commonest we have to deal with. The wound received during the dissection of the dead body is seen only in this locality, and various kinds of poisonous or irritating agents come in contact with this portion of the body only.

The mischief resulting from a "dissection wound," as it is called, gives the usual characteristics of various conditions of inflammation. There is action either analogous to that attending abscess, ulceration, erysipelas, or certain forms of whitlow. On the three conditions first named no special comment is now required, as each has already been considered in previous chapters, but that named whitlow is in many respects so peculiar, that some separate notice of it may be appropriately introduced here.

Whitlow, or onychia as it is technically called, may be the result of the peculiar poisoned wound above referred to, although it must be admitted that it usually has some other cause. The disease itself is met with in various forms. It may be characterized as an inflammation, in one instance, involving the skin or cellular tissue immediately underneath, or, in another, including more or less distinctly and seriously all the component parts of a finger. Sometimes several fingers are involved at the same time, but usually one only is affected. The severer forms of whitlow have sometimes been designated as inflammations of the sheaths of the tendons, but I must say that I have never seen proof that these tissues are in any way more involved than most of the others in the finger. Sometimes the nail, being seemingly too broad, at one or both margins, causes ulceration, probably redundant granulation, and such conditions, if not attended to, cause increase of action in the end of the finger, so that great swelling may be the result, and by continued irritation, a state of chronic enlargement may ensue, involving both soft tissues and phalanx, resembling the figure here depicted (fig. 79). The term onychia maligna has been applied to this form of disease, but in reality there is no true malignancy in it. If, in the earlier stages, the nail be properly pared, or if a section be taken from its margins, the soft parts will get well spontaneously, a result which may be hastened by the application of nitrate of silver to the redundant granulation; indeed, such an application will sometimes suffice without interference with the nail, but in such a condition as that represented in the figure, amputation will probably be the best step, and the wound, being made in the healthy parts immediately above, will heal as readily as under other circumstances, without the smallest chance of any unhealthy or
malignant action remaining or occurring afterwards. Such a state of disease is comparatively rare in the fingers; it is perhaps more frequently met with in the great toe. The more ordinary form of whitlow is in the shape of abscess in the skin at the tip of the finger. Here suppuration may occur between the cutis vera and cuticle, perhaps the simplest of all forms of whitlow, or in the substance of the skin or tissue underneath. Possibly it may have its origin or principal seat in the periostea, or bone, although it is not customary to refer to the disease as having its rise in these latter tissues. It is, however, common enough to see them affected in the progress of a whitlow. The inflammatory action may be limited to the end of the finger, or it may be principally over any single phalanx, or it may involve more or less severely the whole finger. Generally its chief seat is on the palmar aspect, sometimes it is on the dorsal, but usually when the finger is extensively involved, the whole circumference is affected. Often such diseases arise spontaneously; occasionally the ulceration at the margin of the nails may be traced to venereal causes, as in the fingers of medical men engaged in obstetric practice; I have on several occasions seen the worst form of whitlow in stablemen, who have washed the leg of a horse affected with "grease," and poulterers seem to me particularly liable to this affection in its severe form,—from a poison possibly analogous to that supposed to be in the recently dead body.

This figure (fig. 80) represents a finger in the state in which it was amputated for whitlow in one of its worst forms. The part is greatly swollen; various openings are upon its circumference, and these lead to sloughs of tendons and fibrous tissue, open joints, and dead bone.

Whitlow in its ordinary form is a very painful disease, and in severe cases the finger is apt to be seriously injured, if indeed, it be not incurably damaged. Perhaps from the unyielding nature of some of the tissues, pain is greater here than in some other localities, and undoubtedly from this quality there is greater risk of the inflammation doing harm. If pus forms in the deeper parts, it does not readily get to the surface, and its presence produces further mischief. Matter may accumulate in the sheaths of the flexor tendons; periostea may be separated from bone, the bone may be partially or completely killed, or joints may be involved in the worst possible way.

All the conditions above referred to can be readily appreciated, and treated accordingly by any one acquainted with the principles of surgery. It certainly must be admitted that the highest surgical skill often fails to prevent mischief, and very frequently the member is irretrievably damaged by the inflammatory process. It is a common custom to make free incisions into fingers severely affected with
inflammation, and possibly relief may be given by permitting the escape of blood, serum, and matter should it be formed, as also by relaxation of certain tissues, but I have great doubt if these incisions conduce much to the after good of the finger. In small and superficial abscesses a puncture properly timed may give great relief, but if a deep and free incision be made down to the tendons or bones, there will probably be sloughing immediately after, and at best, serious stiffness is sure to result. In some of these instances it may be a question whether the disease or the knife has caused most mischief; but even to admit the latter free of blame, the surgeon, and patient too, should be prepared for bad consequences when the inflammation has gone so far as to necessitate this practice. I have often, in such instances, seen the sheaths so opened, as to permit the tendons to start to the surface of the wound. At first they have appeared quite healthy, but ere long sloughing has taken place. Now although sloughing may take place in tendons irrespective of any interference with the sheath; and although sometimes, when tendons are exposed, they do not slough, I have never seen that the surgeon has had much cause of congratulation after such free use of the knife.

Sometimes a finger will get well after whitlow without any damage, or that, if present, may be very trivial. In other instances there may be stiffness of one or more joints, or possibly loss of substance from sloughing or exfoliation. Often the destruction of tissues seems so great during the active state of the disease or immediately thereafter, that amputation is resorted to, and I believe that in most of such cases much suffering and after-annoyance are thus avoided. But in certain doubtful cases, it is well to bear in mind that great apparent evil passes away after the separation of a portion of bone. I have had occasion to make this remark so frequently in cases of whitlow, at the tip of the finger or thumb, where a portion or even the whole of the phalanx has become necrosed, that I prefer waiting patiently until it gets loose, so that I may pull it away instead of amputating. Figure 81 shows a distal phalanx which was removed under such circumstances. That of the thumb is frequently thus affected, and in such instances I believe, from what I have seen that, the periostium remaining, a new phalanx is gradually developed. The sentient part of the finger is thus preserved in greater perfection than if a knife were applied. Some patients obstinately refuse to permit amputation, however extensively the parts may be damaged by disease. Usually in such instances, after the sloughing and exfoliation have had their course, the sores heal up and the disease is cured. But the part is often found to be so inconveniently in the way, that amputation is afterwards desired. Some surgeons dissuade from amputation under almost any circumstances, but I doubt if they here show the highest exercise of judgment or skill, for there can be little credit in saving a part which will ever after be a hindrance to the free use of the hand,
an eyesore, and an everlasting proof of the limited powers of the healing art. Much though mutilation is to be deprecated, surely a well-planned amputation would be more satisfactory in its results than the condition here referred to. The tip of a finger is peculiarly valuable, and much superior to the end of a stump resulting from amputation. I have seldom had a more gratifying example of conservatism than is here represented (fig. 82). A professional brother, much engaged in obstetrics, suffered from the chronic effects of a severe inflammation in the middle finger of his right hand. Instead of amputating I removed the second phalanx in a necrosed condition, and something infinitely better than a common stump (fig. 82) was the result.

Fig. 82.

The inflammation of whitlow often extends beyond the fingers into the hand, or up the fore-arm, sometimes producing irritation in the axilla; but this usually subsides after the disease in the finger has passed its acme. In rare instances a form of inflammation in the palm of the hand is met with, analogous in some respects with whitlow; indeed I have known it as a continuation of that disease, but it may arise without the fingers being involved. The worst cases that I have seen, have been from small punctured wounds, into which some irritating material has been introduced at the time. I once saw a case of this kind in a blacksmith of Herculean frame. A bit of rusty iron wire had passed slightly into the palm at the root of the middle finger. Intense inflammation followed in a few hours; the arm became much swollen and erysipelatous; and ere matter was formed anywhere, death occurred, to all appearance from intense pain. A deep abscess in the palm of the hand is always exceedingly painful, and as soon as there is any indication of matter, an incision through the aponeurosis should be made at an early date. The knife must never be applied so high in the palm as to endanger the superficial palmar arch; and lower down, the best way to avoid the chief arteries and nerves will be to cut parallel with their course.

The inflammation which follows certain kinds of interference with chronic effusions into the sheaths of the tendons in the fingers and at the wrist, may in some respects be likened to the inflammation above described and alluded to, but I may refer, for further information on such subjects, to the chapter on Incisions a little further on.

Tumours of various kinds are frequently met with in the upper extremity, and cases will be noticed in subsequent chapters. Some of these are in or immediately under the skin, others are connected with tendons or their sheaths, occasionally they are met with in the substance of a muscle, often, perhaps, between muscles; and it frequently
happens that a bone is the original and chief seat of adventitious growths. Such cases present the usual characteristics of tumours; the fatty, the encysted, fibrous, osseous, osteo-sarcomatous, and medullary are all met with in this locality, and such of them as require special notice will be found adverted to in the succeeding portions of this section of the book.

Affections of the nerves are by no means uncommon here, and notices of such cases will be found afterwards.

Diseases of blood-vessels requiring surgical interference are comparatively rare in this locality. Examples of aneurism by anastomosis are seen from time to time, and a singular instance of the kind is noticed at p. 148. Aneurism from injury of the brachial artery during venesection, used to be very common, but it is rarely met with now, owing perhaps to a better knowledge of anatomy than prevailed in former times, but more probably to the circumstance that blood-letting with the lancet at the elbow is now resorted to with comparative rarity. Special notice will, however, be found in a subsequent chapter on this subject. Spontaneous aneurism of the ordinary kind seldom if ever occurs in the upper extremity, excepting in the axillary or subclavian artery, in which vessels it is by no means uncommon. The practice of surgery in all such cases will be brought under notice in future pages.

Various malformations and distortions in this extremity will also be duly considered in subsequent chapters, and separate reference to fractures or diseases of joints does not seem particularly requisite here. I may, however, refer to a peculiar stiffness which is sometimes seen in the elbow or shoulder-joint, while a doubt exists, from the absence of most of the usual indications, as to the presence of actual disease. Sometimes a person has a slight uneasiness, or such a degree of tenderness about the elbow-joint, as may lead him to carry it slightly bent in one position for weeks or months, and then when any attempt is made to extend the arm, it is found that the joint is in a great degree stiff. In the shoulder something of the same kind occurs, but the symptoms may be a little more conspicuous. There may be a deal of pain about the joint, although no swelling; possibly, the deltoid may seem less bulky than usual; the fore-arm and hand may be used tolerably well, but most movements at the shoulder-joint, especially attempts to raise the arm from the side, will be accompanied with pain, and on attempting to move the head of the humerus, an amount of rigidity will be observed, much more than might be expected from a casual glance at the outlines of the joint. A careful examination in such cases will usually detect some tenderness which can only be accounted for by inflammation. My opinion is that in many such instances there is a sub-acute inflammation in the synovial membrane and cartilages, that has a great tendency to lead to fibrous ankylosis, and possibly ultimately to union by bone, if indeed no worse evil befals; and in all such examples I am disposed to recommend local treatment for inflammation, besides such specific constitutional means as the circumstances may seem to demand. In many persons a
rheumatic or gouty disposition may be apparent, and colchicum, iodide of potassium, with such other general means as are usually resorted to in such constitutional affections, should be in requisition also.

It has been found difficult in the arrangement of the contents of this volume, where to place the subject of diseases of the mamma. The section on tumours might have been a suitable position, or that referring to the surgery of the chest would have done, but I have thought it best to introduce the subject in this section.

There is no single gland in the body more subject to disease than the mamma, and as many such cases are of the most formidable nature, they are full of interest, as well to the surgeon as to the patient. More has been written on the mammary gland than on any other gland in the body, and the principles and pathology of surgery have been largely drawn upon to illustrate the subject. Besides it must be admitted, that some of the worst characteristics of certain forms of disease are best exemplified in this part of the body.

It will neither suit with the arrangements of this work, nor does it seem to me essential to its intended practical character, that a minute detail should be given of the various diseased conditions met with in this organ. I shall prefer limiting my observations to such subjects as appear to me to bear chiefly on the ordinary practice of surgery.

Inflammation and its consequences in this gland, often give rise to much distress. It is seldom that such cases are met with prior to child-bearing, and some have the idea that certain forms of abscess can occur only after the birth of a child. Undoubtedly inflammation of the mamma is seen most frequently during the early period of lactation. Often it seems to follow so directly the occurrence of chaps and ulceration in the nipple that it may be said to be occasioned by the continued fretting of the infant's gums, but perhaps it appears often independent of such a cause. Inflammation of the mamma under such circumstances frequently ends in suppuration, and the condition is often called milk abscess, but a similar state may arise before a child is born, and one of the most severe cases of abscess in the breast I ever saw occurred during the seventh month of pregnancy. Neither is it correct to attribute bad forms of this affection on all occasions to the irritation of sucking, for in some of the worst cases this has never been permitted. It is, perhaps, impossible to discover a direct cause of severe inflammation in many such instances, but certainly it is well to bear in mind that continued irritation at the nipple may be the source of much mischief. In most cases the necessity for suckling is obvious, and then the surgeon should try the effects of various astringents in the shape of lotions, or ointments to the part; solutions of the subacetate of lead, acetate or sulphate of zinc, sulphate of alum, and such like, should be used. Carbonate or oxide of zinc ointments, citrine ointment, an ointment containing nitrate of silver, or this salt in solution, or in stick, may be applied, and possibly with advantage; or the part may be protected with a tent, or with the modern application of collodion. But whatever may be done, even by the most skilful, evil consequences cannot always be avoided. In spite of leeches, fomenta-
tions, and all other means likely to keep back inflammation, the disease will run its course, and suppuration will ensue. There may be one abscess or several. Matter may form in the substance of the mamma, underneath it, or near the surface, and occasionally it appears as if one or more of the larger milk ducts were the seat of suppuration. The formation of pus in the mamma is attended with great suffering, and it becomes impossible, in most instances, for the female to give suck in the affected breast. In all instances there is usually much swelling, and the weight of the part is considerably increased. Due support is, therefore, of considerable importance in such cases, and as soon as matter can be recognised by the external touch, an opening for its exit should be made. All such incisions in this locality should run like radii towards the nipple, so that the least possible damage should be done to the milk tubes. Several openings may be required, although, in general, one will suffice. If the knife has to be carried deep, there may be some troublesome hemorrhage, but this event more frequently occurs when the surgeon has to treat abscesses in their chronic form, when they have assumed the condition of sinuses. Here, when the knife has been used, I have known very troublesome bleeding, and, in some instances, it has been requisite to enlarge the external opening. Sometimes, after extensive suppuration of the breast, it is left with such numbers of external apertures and deep-seated sinuses, that one really knows not well what to do. I have seen the breast amputated under such circumstances, but hardly anything would induce me to accede to such practice. I have in many such instances cut the breast open in all directions, especially at the circumference, with the most satisfactory results. Once where I had treated obstinate abscesses in this way, to a far greater extent than I had ever ventured upon before, my impression at the time was that the breast might as well have been removed, but I learnt that after a subsequent pregnancy, this patient had not experienced any annoyance, and had suckled her infant as if no such damage had previously been done. Possibly this satisfactory condition may have been favoured by the general rule acted upon of cutting as little across the ducts as possible. Of course it must be understood that all the usual means of getting sinuses to close have been resorted to ere such practice as that just spoken of is enforced.

The "irritable mamma" is a condition which requires constitutional treatment more than local, and it does not seem to me to need special comment here; neither shall I dwell upon the various forms of tumours which occur in this locality. Every now and then cases are met with of induration in the mamma, simulating in most respects an ordinary tumour, which, however, ultimately turn out to be chronic abscess. I have seen various such, where all the preparations were ready for excision of the breast, when, owing to some suspicious circumstance, the step has been delayed, and the case has changed clearly into an abscess. Whatever tumour or induration be present, it is always of importance, when there is doubt, to look at a case repeatedly and very carefully ere such a step is resorted to. Sometimes a
simple fatty tumour in this situation gives rise to much difference of diagnosis, as the rarity of such cases probably constitutes the difficulty of recognising them. I have met with several examples of the kind.

All indurations or distinct tumours of the fully-developed mamma must be looked upon with great suspicion. In some instances a little hard mass will form not far from the nipple, which may for a time occasion anxiety, fluctuation may ultimately be felt, and possibly ere this the patient may have noticed a dark coloured discharge from the nipple. Here slight dilatation of a mammary tube may permit the fluid to pass away, and from time to time a repetition of this, with a little pressure, may allay all apprehension. I have watched some such cases for many years, and never seen further evil. In other cases, indurations, or rather small round tumours form about the circumference of the mamma, and doubts are entertained whether these be in the mamma, or only in juxtaposition. Perhaps, after all, when a question arises about these, it has reference chiefly as to whether the disease, simple though it may appear, is in reality a benign growth, or one of a cancerous or malignant character. My own impression is, that in many such cases no one, let his skill be what it may, can positively decide such a question by external manipulation. These are for watching, and the ordinary means to cause the dispersion of tumour; but, assuredly, if a question is put as to the safest course for a patient's welfare, I should recommend an operation. If after-examination of the tumour induces a belief of its benign character, the patient, and surgeon, too, may be well satisfied with a positive knowledge to this effect; and if, on the contrary, there be anything to excite suspicion, or give reality to expressed forebodings, then both parties may be well assured that all has been done for the best.

In young unmarried women small hard tumours about the size of a hazel-nut are not uncommon. They are more frequent about the circumference than in the central parts of the mamma. When first observed they are about the size named, but often they attain the bulk of an orange. Generally they are single, but two or more may be in the same gland. They may usually be distinguished by absence of pain, hardness, elasticity, and distinctness of circumference. When skilfully removed—i.e., without interfering with the mammary substance—they present a nodulated appearance, with a smooth, glossy, fibrous investment, showing a perfect isolation from the gland, and a section confirms the fibrous aspect of the mass. It has become the custom of late to refer to these tumours under the name of adenoid. Their diagnosis is of much interest and importance. If removed at a reasonably early period, the mamma may be left entire; but in the course of time attachments will be formed which cannot be divided, and thus for safety more mammary substance may be detached than absolutely necessary. I have good reason for stating that in some of these cases even the whole mamma has been recklessly removed, when a sounder pathology and discrimination on the part of the surgeon might have obviated such an unfortunate mistake. At first they are
distinctly non-malignant; but I have an impression that in the course of time they may degenerate. They may become fibro-cystic and fibro-recurrent, and I consider it unwise to allow them to remain long after they have been detected.

The larger forms of growth give rise to less hesitation; for, with few exceptions, they all ultimately require operation, or must be abandoned to work their influence on the constitution.

In many instances of tumour of the mamma I deem it impossible to decide on the true character of the disease, until it is actually removed from the body. In reality, a majority of such cases are malignant, and such I think is the practical view to take of them. The character of the pain in some such instances I deem of little importance, unless, indeed, the surgeon could decide between that of chronic abscess and scirrhus. I have known a tumour of two or three years' duration end in abscess, but that is a rare case, and for myself I do not presume to decide, between the pricking lancinating pain in scirrhus, or the duller or possibly throbbing pains of incipient abscess. Certainly, the hardness of a tumour in the breast ought to induce the fear of scirrhus, especially when joined with retraction of the nipple, but then the nipple may be quite prominent in medullary sarcoma,—soft cancer, as it is now often called,—although in reality it may be well nigh as hard as scirrhus, especially in the early stages; and although much has been said about retraction of the nipple being a diagnostic as to malignancy, it seems to me of little real utility in this light, for another kind of disease, equally malignant as scirrhus, may be present without any peculiar change in the nipple, and it may actually be retracted in a benign tumour.

In such cases I take it always as a good sign when the glands in the axilla are not enlarged. In abscess they may be so, but then the abscess is usually easily recognised. In simple tumours of slow growth, they are, perhaps, never affected; whereas in malignant disease long time will not elapse ere they are enlarged, either from sympathy or from the commencement of disease like that in the breast.

Whatever be the nature of such tumours, the grand object of the surgeon is to get rid of them or arrest their progress without having recourse to the knife. Unhappily, however, he has little power in this way. On the supposition that the action accompanying such diseases is one of excitement, analogous to that of inflammation, leeches have been freely used, and in most instances they give some relief, as regards pain, but no ultimate good need be expected from them. Perhaps the fomentations used after leeches may contribute to relief in such cases; and I think so highly of stupefying, in most instances, that I almost invariably recommend it, whether leeches be applied or not. If the surface is kept constantly moist by a wet rag and oil-silk, the swelling often gets softer and more free from pain; but it would be fallacious to trust to this remedy to give permanent immunity from disease. The various methods usually applied for the dispersion of tumours, may be tried here at the discretion of the surgeon, and among them, iodine in its various forms may be pushed to
any reasonable extent; but I would warn the young practitioner not to be sanguine in his hopes of success. Pressure by means of a bag of air, or water, in accordance with the views and recommendations of Dr. Neil Arnott, may be tried, but little good can be expected from this plan either. In one instance which was sent to me for operation, I tried this mode of pressure; and had every reason to be satisfied. The swelling diminished in size, and twelve months after there was only a small hard mass round the nipple, which gave no inconvenience; but in many other cases in which I have resorted to the same method the result has not been so gratifying.

Whatever advances may have been made in the pathology of tumours in modern times, and however much we may feel indebted to the industry of Mr. Birkett and others for additions to the subject since Sir Astley Cooper's time, it must be admitted that we are little advanced in therapeutic influence over such affections. Indeed I have sometimes had my doubts whether surgery has not taken a retrograde direction in this department; for, notwithstanding the elaborate investigations of Professor Walsh, tending to show that operations for cancerous affections here are frequently followed by return of the disease or by other unfortunate results, I cannot but think that a close reliance on such views is questionable. Every surgeon of experience must very frequently have had occasion to lament the inveterate character of such cases, as exemplified in the return of the disease for which he has already performed an operation, yet I doubt the propriety of deciding against operations in all cases, because the disease so often recurs. On the whole, after a careful consideration of my own experience, I confess that, although I have often operated with great reluctance, and under most disadvantageous circumstances, I am still disposed to recommend the proceeding in properly selected cases, and I have in my recollection numerous examples where patients have lived many years free from recurrence of the disease. Without an operation the generality are beyond a cheer of hope. Such operations are rarely fatal, and usually on recovery, the bodily, and especially the mental relief are so great, that they counterbalance the gloom of a possible return. Besides, in many instances, a return of the disease, which happens usually near the cicatrix of the former wound, is not so formidable as the original affection, or rather, more strictly, such a condition may be operated upon again, before the disease has assumed the bulk or appearance of the former tumour. I have known a second, or even a third operation less formidable than the first. But much judgment is required in deciding the proper course in such cases. We have even the high authority of Sir Benjamin Brodie,—although like all other experienced surgeons averse to such operations in general, that the knife may be used actually in certain cases which have run to ulceration. In such examples the surgeon will be still more cautious than he would be in less advanced forms of the disease. It may be reasonably expected that some criterion should be given here, as to what may lead to a decision for or against an operation. I think it almost impossible in words to convey a correct idea on such a point. I should say as a
general rule, that if the skin be much affected in such cases, or if the axillary glands be numerously or considerably enlarged, an operation should not be resorted to. The usual state of the health otherwise, as we would judge of it with reference to any other operation, must be duly taken into account, and should there be reason to suspect that the local disease has tainted the system, it would be unwise to interfere. Notwithstanding all that has been said and written on this subject, my own impression is, that as yet we have no data for deciding as to whether the various forms of cancer which attack the mamma be constitutional or local. It is rare indeed to see a cancer in the mamma and in other organs at the same time; and even when persons die of the disease, its chief characteristics are usually in the immediate vicinity of the breast; nevertheless, in the advanced stages, there is usually that waxy state of the skin, and cachectic condition generally, which too truly denotes malignant influence. But I may now refer to some additional observations on such subjects in the chapter on excision of the mamma, in an after portion of this section of the volume; and in here drawing this chapter to an end, I must beg the reader to bear in mind that my object in writing it has been chiefly to direct attention generally to such matters as may be deemed peculiar to the upper extremity, and which will be treated at greater length in subsequent chapters, or in the first section of this work which is devoted to the general principles of practical surgery.

CHAPTER II.

DISLOCATIONS.

Dislocations in the fingers are of frequent occurrence, and often of such a nature as to induce the surgeon to remove the injured part by amputation. In such instances, in addition to the displacement, the bones may be broken, the soft parts extensively injured, and a joint or joints laid open. 

In simple dislocation of one phalanx from another, the end of the lower bone will ride over that of the upper either above or below; as is represented in the two figures (83 and 84), in which, for the sake of clearness, the phalanges are exhibited divested of all coverings. I need scarcely add, that the distal joint may be dislocated in a similar manner, although it must be admitted
that these displacements in the fingers are more rare than some appear
to suppose.

Lateral displacement in any of the phalanges rarely, if ever, happens
without severe de-
struction of the parts; as, indeed, may be
conjectured from an
examination of the
joints; and, in such
cases, amputation may
possibly be required.
In all probability the
dislocation will be
compound, and there-
fore, taking the risk of severe inflammation, and also that of a stiff
joint, into consideration, I imagine that removal of the part will often
be the best course; but more will be said on this subject in the
chapter on fractures, with which injuries those at present under notice
are not unfrequently associated.

For the reduction of a simple case, as above described, the patient's
hand must be held firmly in the left hand of the surgeon, who should
grasp the lower part of the finger with his right, somewhat in the
manner shown in the next drawing, when, by steady extension, the
lower phalanx will slip into its proper place. In most instances
success will be more rapidly attained by gently moving the lower part
of the finger upwards and downwards, and in some it will be ad-
vantageous to bend the member with considerable force towards either
the back or palm of the hand.

Simple dislocations of the fingers from the metacarpal bones are of
more frequent occurrence than the above; and the fore or little finger,
from their comparatively unprotected position, are most exposed to
those forces which cause displacement. The phalanx will be either on
the palmar or dorsal surface of the metacarpal bone, most probably
the latter, and may, in general, be readily reduced by following the
foregoing instructions. The surgeon, by grasping the finger nearer its
root, as seen in this figure (85) of a dislocation of the index finger

backwards, will have all the advantage of a firmer hold, and a more
powerful lever. The middle and ring fingers are so well protected by
their position, that dislocation of the head of either on the metacarpal bone is of rare occurrence, unless the injury to the hand is severe and complicated. Even such a luxation as that represented in figure 85 is of rare occurrence; and the same may be said regarding the little finger.

The phalanges of the thumb may suffer like those of the fingers, and

Fig. 86.

the preceding observations are equally applicable here. The distal joint is seldom the seat of simple luxation,—the proximal phalanx being the one most frequently displaced; and it may be either in front or behind the end of the metacarpal bone, as exhibited in the accompanying figures (86 and 87).

The displacement of the first phalanx backwards (fig. 87), or, as some describe it, of the metacarpal bone forwards, has attracted considerable notice in consequence of the trouble frequently attending reduction, and the occasional impossibility of attaining this object. It is difficult to account for this in a satisfactory manner from any peculiarity of the articulation, as evinced in the bones or ligaments. Mr. Hey imagined that this difficulty was occasioned by a kind of wedge-shape in the end of the metacarpal bone, the thickest part of which, being thrust between the lateral ligaments, presented such an obstacle to reduction, that, if these remained entire, it was almost impossible to replace the bones. Though I have never been fully satisfied of the correctness of this view, I am not prepared to deny it; and in a somewhat similar mode of reasoning, I am inclined to think it not improbable that in some instances the large extremity of the metacarpal bone being driven between the two portions of the flexor brevis, as well as between the lateral ligaments, (which, however, in such a case would doubtless be extensively stretched, or perhaps torn across,) combined with the vast power of the numerous muscles connected with the first phalanx, may be the chief cause of the difficulty experienced in these cases; more particularly when the shortness of the lever which the surgeon has to work with is taken into considera-
tion. I have seen an instance of compound dislocation in this joint, where the end of the metacarpal bone projected through a transverse wound of the textures on its anterior surface, in which the bones could be reduced and displaced with facility, twelve hours after the accident, and it seemed to me that the lateral ligaments were as entire as if there had been no external wound. Anhylosis occurred in this ease after severe inflammation and suppuration.

In instances of this dislocation where the ordinary means fail, it seems to me very doubtful if such a measure as removing the end of the metacarpal bone, through an incision made directly upon it, should be resorted to; for, although such a wound may occasionally heal by the first intention (as was long ago noticed by Mr. Hey, in referring to some cases occurring in the practice of Mr. Evans of Ketley, who in two instances cut down upon the extremity of the metacarpal bone, and removed it with success), there would certainly be great risk of its not doing so, and in such an event, the results to the patient would be much more painful and annoying, whilst in all likelihood the member (provided it escapes amputation) would be of no more service than if it had been left in its distorted condition. It is well known, and I have seen such examples, that in the course of time, a thumb in this state is gradually restored to much of its original utility.

To facilitate reduction, the old proposal, of dividing one of the lateral ligaments, might now be practised with greater propriety than in former times, by performing a subcutaneous operation, with a very small and narrow-bladed knife: indeed, by a similar proceeding, the opposite ligament might also be cut in the same case, or any other texture that seemed to offer resistance,—the wound, or wounds, in the skin being so small, that little fear need be entertained of any bad results following the discreet use of such an instrument.

Dislocations in either thumb or fingers can occasionally be reduced by simple pressure, with the surgeon's thumb and fingers, on the displaced end of the bone, and it is often of service combined with extension as above described; but in some cases neither of these means will answer, and a greater degree of extension must be applied. In such instances, a bit of tape, a silk handkerchief, or soft calico bandage should be slipped round the lower part of the disjoined member, and the ends given to one assistant, whilst another keeps the hand steady. The surgeon can then use his fingers in such a way as he thinks most likely to be of service. The pulleys (afterwards delineated) have even been resorted to in some of these cases! and we need scarcely, therefore, wonder at the instance alluded to by Bromfield, in which the end of the thumb was torn off by an over-zealous attempt of a surgeon to effect reduction.

The noose will be best fixed by casting such a one as this (the clove-hitch, as it is often called), fig. 88, which can be readily imitated with a bit of string. First one circle is made by turning the string from one side to the other (right to left), then a second in the same way; if that last made is now placed behind the other, and the two loops are put
on the part where the extending force is to be applied, and drawn sufficiently tight, a noose will thus be formed that will not readily slip off, nor will the extending force have any effect in tightening it to an injurious extent round the member.

Before applying a tape or bandage, it may be well to protect the skin with a small bit of lint: and, in fixing either of the former, it may be put round the thumb beyond the displacement, or above the end of the metacarpal bone in such a manner that the extending force will act chiefly on this part.

In the summer of 1869 I saw Mr. George Pollock cleverly reduce a dislocation when the upper end of the proximal phalanx lay in the palmar side by means of forceps like these (fig. 89). The bits of leather are so attached to the grasping parts of the blades that they close upon the thumb as the handles are pressed by the surgeon. The lever force here is of great value, and the instrument is applicable alike to finger as to thumb.

The metacarpal bone of the thumb is sometimes dislocated from the os trapezium. Sir Astley Cooper has described the displacement towards the palm as the only kind which he has met with, and has advised that unless the reduction could be easily accomplished, the parts should be let alone. I have not met with any example of this kind, but have seen several where the end had slipped backwards: in two cases the injury was occasioned by strong force having been applied at the distal extremity of the bone. There is little difficulty in reducing the projecting point, but there is much in keeping it in its proper place. I have seen a splint and roller fail to do so. When it shows a tendency to slip out of its situation, a strong narrow bit of pasteboard, wood, or gutta percha, should be laid along the lower extremity of the radius, over the entire length of the metacarpal bone, and retained by means of straps of adhesive plaster, or a bandage, for the space of three weeks, when the best possible chance will thus be given for the parts keeping their natural position.

The bones of the carpus are but rarely separated from each other, and only when great force is applied. In many such cases amputation
will probably be required; yet it may occasionally be good practice to attempt to save the hand, after removing one or more of the loose and perhaps shattered bones. The os magnum is sometimes thrust backwards, however, without irreparable injury being done to the neighbouring parts. In such a case, if the bone cannot be at once pushed into its proper place by the surgeon's thumb, no other attempt should be made, lest it aggravate the evil, by inducing inflammation and caries of the carpal bones. I have seen amputation above the wrist required in consequence of injudicious interference in such an instance.

I have known of one example, in which the pisiform bone was detached from its lower connexions by the action of the flexor carpi ulnaris. Little benefit can be expected from any attempt to keep this bone in its proper position, nor, indeed, is the displacement of much consequence.

No special allusion to the symptoms of the luxations above referred to has been made, as it is presumed that any one acquainted with the general characters of luxations, and with the anatomy of the hand, will at once make out the true nature of each. The carpus may be displaced either backwards or forwards, or in a lateral direction. In the latter case, the dislocation cannot be complete without great injury, which may possibly necessitate amputation. In the former of these examples, the hand with the bones of the carpus may be deemed the moveable parts, as indeed they really are.

When the first row of the carpus is driven from the articular surface of the radius, in a direction backwards or forwards, the projection thus formed, and the corresponding one on the opposite side, can leave small doubt of the nature of the injury. The two skeletons here delineated (figs. 90 and 91) will give a tolerably correct idea of
each of these luxations, although it should always be remembered, that in the living body the appearances owing to the effusion of blood and swelling, may not be altogether so clear. With these sketches, as with those of the fingers and thumb, the state of flexion is such as, I believe, will generally be met with in practice, although occasionally the angle may be more or less acute, as most surgeons of experience must have noticed.

Little difficulty will be met with in reducing these displacements, provided they are seen at an early period. After the lapse of ten or fifteen days, it may be a question whether or not it will be safe to apply much force. I have seen one case where reduction was accomplished with tolerable ease after fourteen days, and all went on favourably afterwards. In this instance little force was needed; and in all similar examples violent force or twisting is to be deprecated, for fear of exciting disease in the carpus.

In reducing these luxations, an assistant should steady the fore-arm, whilst the surgeon applies the extending force either by grasping the patient's hand in his, or by means of a handkerchief twisted round the part above the thumb. A slight degree of flexion or extension cautiously applied will facilitate the object in view.

The radius and ulna are sometimes separated at their lower extremities. The ulna appears to be detached from the radius in such cases, and the prominence caused by its extremity leaves no doubt regarding the nature of the injury. A little pressure suffices for replacement, but it will not remain unless retained by a bandage, and even then there will, perhaps, be a projection, which fortunately, however, is productive of little or no after inconvenience; indeed, in many persons advanced in years, a kind of slow spontaneous displacement of the lower extremity of the ulna occurs naturally, which causes no annoyance whatever.

One or both bones of the fore-arm may be displaced from the humerus. The head of the radius may pass in front of the external condyle, or it may be behind it. Figures 92 and 93 give illustrations of these two. In either instance the injury is most likely to be occasioned by the patient falling, and attempting to save himself by throwing out his hand. If the head of the bone be in front of the condyle, it may possibly be felt in that situation; the comparative

Fig. 92.

distinctness of the external condyle, the semi-bent position of the arm, and the inability to bring the hand up close to the shoulder, will all
serve to indicate what is wrong; and if the displacement be on the back of the condyle, the head of the radius would be readily felt, if not seen, in that situation. The rupture of the annular ligament must, in these examples, precede and facilitate the displacement. From the frequency with which the luxation of the head of the bone forwards is met with in the dissecting-rooms, I am inclined to think that the accident is often overlooked; and I believe it to be much more common than that backwards. My own experience, especially in the dead-room, leads me to suppose that Sir Astley Cooper's estimate of the relative frequency of these two injuries is the most correct, although it is worthy of notice, that, while he states the dislocation forwards as being the most common, Boyer asserts, with equal precision, that the head of the bone passes most frequently backwards.

In old standing, neglected, or overlooked cases, when the head of the bone rests in front of the external condyle, it seems to produce little inconvenience, saving a slight diminution in the motions of flexion and extension, more particularly the former; and the same may be said regarding the luxation backwards. In either instance if the head of the radius seemed to be much in the way I believe that it might easily be removed without much danger, and with great advantage. In so far as I know, such an operation has never been performed, but it is one which I have adverted to for many years in my surgical lectures.

In all instances, however, where either of these injuries is detected at first, the head of the bone should be drawn, by extending or bending the elbow, or perhaps thrust at once into its proper position, and whenever there is difficulty, the motion of supination or pronation may probably facilitate the proceeding in either case. As it may be a little troublesome to retain the bone in its natural place, the best chance will be given by keeping the elbow-joint quiet, and in a bent position, by means of a bandage; and should great steadiness and some considerable pressure be required, then a splint, similar to that used for fractures in the lower part of the humerus, may be had recourse to.

The bones of the fore-arm can scarcely be dislocated forwards on the humerus without a fracture of the olecranon process, and the conjoined injury I believe to be very rare; they are, however, not unfrequently displaced backwards, as represented in fig. 94. The unnatural prominence, both in front and behind, as well as the fixed position of the bones, will sufficiently indicate what is wrong, and the nature of the accident will be readily made out by any one acquainted with
the anatomy of the joint. In such a case the coronoid process will probably be broken, and the displacement not really so great as here represented.

One of the most distinct cases of this luxation which has ever come under my notice occurred in a boy of about ten years of age, who, in playing at leapfrog with his companions, fell upon his hands, and thus sustained the injury in one arm. I have seen many of a similar kind, and I believe that the accident frequently happens in falls from horseback. The prominence of the olecranon, the distinctness of the head of the radius, and the fulness in front, caused by the lower end of the humerus, all very clearly indicate the character of this injury.

If this accident is seen by the surgeon shortly after its occurrence, and before much swelling has come on, it can readily be detected, and the two bones can be drawn down with little trouble into their proper situation. The forc-arm, which will be a little bent at the joint, should be drawn down in the axis of the humerus, and, by bending it a little further, in all likelihood the bones will be replaced. An additional force must be applied, should there be much difficulty; but care must be taken, particularly if the injury be of some standing, not to apply a great degree of violence, as this may be productive of more serious injury to the joint, by the additional inflammation thereby induced. Within the last few years I have seen a considerable number of cases of this kind which had been overlooked or neglected, and I have attempted reduction in many, at periods from four weeks to three months, but have never, even under anaesthesia, succeeded in fairly reducing them.

Dislocations of the bones of the fore-arm at the elbow, forwards or in a lateral direction, are of very rare occurrence, and can happen only in violent injuries; the former accident being, as already stated, complicated, in all probability, with fracture of the olecranon.

Any surgeon, however, who has seen much among the lower orders, as in dispensaries and out-patient hospital practice, must agree with me in thinking, that it is impossible to say what dislocations may not take place in this articulation. I have myself frequently seen the joint in such a disordered condition, from injuries of old date (probably luxations and fractures combined), that the most experienced anatomists have been unable to appreciate the true condition of the ends of the bones; and in many of these cases the facility of movement was remarkable, as was also the muscular development of the arm and fore-arm, which was such as to give the parties an excellent command over the extremity. These two sketches of the lateral dis-
placement of both bones,—the one inwards (fig. 95) and the other outwards (fig. 96),—will give some idea of such injuries, although I imagine that on the living body the regularity here delineated would not be so perfect; for the force which would cause such displacements would, in all probability, produce separation of the two bones, and fracture too, perhaps of one or both, or of the lower end of the humerus.

Figure 97 represents a very rare form of luxation in this situation, viz., a displacement of the ulna backwards, with the radius thrown slightly forwards. Such a case has been referred to by Sir Astley Cooper, who mentions two of the kind. I can fancy such an injury being complicated with fracture of the radius, lower down, as also of the coronoid process of the ulna.

In all such cases, there may or may not be difficulty in replacing the bones; and here, as in all other injuries of this joint, whether the
attempt at reduction is successful or not, too much care cannot be bestowed in keeping the limb quiet, and in a bent position. At first, as the patient will be kept to his bed, the arm may be placed on a cushion, and afterwards it should be carried in a sling.

In certain compound luxations of the elbow, complicated with fractures of the coronoid or olecranon process, or of the condyles of the humerus, were the ends replaced, there would be great reason to apprehend severe inflammation, which might probably end in caries of the bones; were the case one, in short, where at the first glance amputation might be deemed the only resource, it would be well to pause and contemplate the propriety of cutting away the exposed and injured ends of the bones, and thus give the patient a chance of having his hand preserved. There can be no doubt that, in many instances, such practice would be better than amputation; but in such as is represented in this drawing (98) (taken from an arm

which I amputated many years ago in King's College Hospital), the soft parts seemed too much injured to encourage me to cherish a hope of saving the limb by such a proceeding as that referred to. The particulars of this case, and my reasons for preferring amputation, were given in the Lancet, October 2nd, 1841: but assuredly in less severe injuries it would be proper to try the chance of saving the limb, without or with excision, as might be deemed most advisable. Even in such an instance as this, however, in the present day I should prefer excision to amputation; and were a similar case to occur to me now, I should have sanguine hopes of saving the limb.

When the shoulder-joint is examined anatomically, it will be readily perceived that its weakest part is below, in the space between the teres minor and subscapularis, where it is not protected either by muscles or tendons, and where, moreover, the capsular ligament is less likely to restrain the head of the bone than at any other point. These circumstances may account for the frequency of dislocation of the head of the bone in this situation. It is impossible in most instances to ascertain the position of the limb previous to the accident, nor is it of much consequence to know whether the displacement has been occasioned whilst the arm has been raised from the side, or by direct

Fig. 98.
violence over the shoulder, as undoubtedly may be the case. In whatever way it may be accounted for, the luxation into the axilla is of more common occurrence than any other sort of displacement in this joint. The bones occupy this position (fig. 99); the head of the humerus rests on the margin of the scapula below its neck, in front of the attachment of the long head of the triceps, and it may be slightly in the substance of the subscapular muscle, as can be imagined from an examination of the drawing. The head of the bone is perhaps a little lower and more on the margin of the scapula than is shown in the drawing. In several dissections which I have had the opportunity of making of recent injuries of this description, I have found the bones as thus represented; the capsular ligament has been extensively torn, with part of the tendon of the subscapular muscle; in one instance the supra-spinatus was greatly stretched; in another, the tuberosity, into which the tendon of this muscle is inserted, was torn off; in all, the axillary vessels and nerves were slightly on the stretch, and in none of these was the circumflex nerve torn. In some examples of this dislocation of old standing, I have found it impossible to trace this nerve throughout its course, as it seemed to have been ruptured at the time of the accident: in others, again, I have traced it with great ease. In the former, I have particularly remarked the atrophied condition of the deltoid muscle, whilst in the latter the diminution in bulk has not been more than might have been expected, as the result of restricted movements in the joint.

The features of this luxation are in general so well marked, that it might be supposed impossible to overlook its nature. Such a mistake is, however, too frequently the case. The history of the accident, the immobility of the limb, the pain and swelling in the armpit, numbness of the fingers, with (in some instances) edematous swelling in the hand, the separation of the elbow from the side, the increased length from the acromion to the olecranon, and, above all, the flatness of the shoulder, should sufficiently point out what is wrong.

The head of the humerus is occasionally thrown inwards and upwards, so as to rest under the pectoralis major muscle, and to be in contact with the pectoralis minor and coracoid process of the scapula, as represented in figure 100; or it may be driven backwards on the dorsum of the scapula, of which I have seen several well-marked examples, which may be understood by a glance at fig. 101. In the
latter case, the humerus slopes slightly forwards, and the head of the bone under the spine of the scapula will be felt in its unnatural position, closer to the spine perhaps than here represented. In the former (fig. 100), the head of the bone may also be felt, though not so distinctly; and the arm will slope backwards and outwards, as shown in the sketch; in both the deficiency under the acromion, the history of the accident, as well as the general marks of dislocation, will indicate the nature of the injury.

Dislocations of the shoulder-joint may be reduced in a great variety of ways; but, as it would be inconsistent with the nature of this work to describe or even refer to them all, I shall merely speak of those which I consider most worthy of attention.

One of the most simple methods of proceeding is as follows:—The patient should be seated on a chair, a table-cloth or sheet, folded to the breadth of eight or ten inches, placed around the chest, its middle being close under the injured part, and its two ends given to an assistant standing on the opposite side; another cloth should be fixed by the middle on the arm immediately above the elbow, and its ends intrusted to a second assistant; the surgeon, placing himself behind the arm, should lay hold of the extremity in such a way as to bend the elbow, and move the humerus in a rotary direction on its long axis, whilst the two assistants are engaged, the one in keeping the body steady, the other in making gradual extension. If this force be judiciously applied as thus directed, the head of the humerus will, in all likelihood, pass into the glenoid cavity with a kind of snap, which will be perceptible to both patient and surgeon. It may, however, be necessary to apply more force by means of additional assistants, and the operator may also require to be more rude in that which he himself exerts. In such examples, if chloroform be not used, the warm bath, the abstraction of a quantity of blood from a vein
in the arm, and the exhibition of plentiful doses of the solution of
the tartrate of antimony, will be of great assistance. But as a
matter of course in the present day the anaesthetic agent will be
preferred.

If success cannot be obtained in this way, a stronger force must be
applied by means of pulleys (fig. 102), which should be used in the

Fig. 102.

following manner:—The patient should be seated on a firm chair,
or on the floor, his body enveloped as above described, and the
ends of the cloth attached to some point fixed in the floor or wall;
the hook of one end of the apparatus should then be fixed in a towel,
which has previously been properly fastened round the patient's arm
above the elbow, and the other hook being attached to a fixed point,
opposite to that above mentioned, the extension may be applied by a
single assistant, who draws by the loose end of the cord. The surgeon,
placing himself on the outside of the arm, should keep it bent, and by
the same manoeuvre as already directed, viz., rotating the humerus on
its own axis, the desired object may be accomplished. In cases of
difficulty, when the extending force is supposed to be sufficiently
applied, it may be of advantage for the surgeon to put his knee into
the armpit, and desire the assistant suddenly to quit the rope, when,
by depressing the lower part of the arm, and using it as a lever, the
knee being the fulcrum, the head of the bone may be forced into its
proper position. On the common principles of mechanics, this plan
might be supposed to answer well; I must say, however, that although
I have often seen it of service, I have observed it to fail, and have
much more frequently noticed the end of the bone slip suddenly into
its natural place during the application of the extending force. Instead
of a sheet, table-cloth, or towel, the surgeon may be provided with a
kind of stock apparatus, which, with the pulleys, and screw represented
on page 222, may always be kept by him in readiness for use. It
consists of an oblong piece of stout canvas, between three and four
feet in length, and about nine inches in breadth at the middle; here
there is a hole of sufficient size to allow the arm to pass through,
close up to the axilla and scapula: and each extremity is terminated
with a stout iron ring. When the arm is put through the hole, and
this broad belt is drawn up to the shoulder, the two rings, by bringing
one before and the other behind the patient's body, can be brought together on the opposite side, and then fixed to any convenient point by means of a towel or piece of rope. The side of the belt next the skin is usually lined with soft leather, to prevent chafing; and it may be well, too, when it is used, to aid in obviating this annoyance by placing a folded towel, or a pad of lint, in the axilla. Another portion of the apparatus consists of a kind of clasp, made of iron and leather, to fix round the arm above the elbow, by means of screws, or straps and buckles. The circle is well padded within, and also lined with leather, and has a couple of belts attached to it, which are provided at their loose ends with a ring each, through which, when brought together, the hook of the pulley is passed. Such apparatus, with pulleys and screws, may be had from any instrument-maker. The belt I deem greatly preferable to a sheet, which, unless a hole be cut in its centre, only offers its resistance below the axilla, whilst the former fixes the scapula in a much more efficient manner. It is of the utmost consequence that this bone should not be acted on by the extending force, but be kept steady and fixed during the act of reduction. The clasp is very apt to slip from the lower part of the arm, and I am inclined to use in its stead a jack-towel, fastened to the arm by the clove-hitch (p. 211), or a thick and sufficiently long and stout skein of coarse worsted thread, which from its softness and elasticity, is less likely than the towel to injure the skin.

The preceding sketch (fig. 103) will make my description more intelligible. The patient is represented as seated on a couch or chair, with the surgeon in the position above described. The body-belt may be supposed to be fixed above the level of the injured shoulder, whilst the pulleys are below; in some instances the latter may be placed highest, and in all it is evident that when the extending force is being applied, there must be a straight line betwixt the extreme points. In addition to the apparatus referred to I advise that a couple of common iron staples should be kept at hand, as they will be convenient to drive into the floor or wall for fixing the body-belt or pulleys,—for the
handle of a door, or bed-post, or bar of a grate, will not offer sufficient resistance in such cases, as I have experienced. Such a screw as that here represented (fig. 104) may be had in the ironmonger's shop, and two, somewhat larger than that in the figure, will answer as well as the staples. Under the supposition that a force sufficiently powerful cannot be applied to the end of the pulley-ropé by the hands alone, Mr. L'Estrange, of Dublin, devised an apparatus consisting of a windlass, cylinder, and appurtenances, with which he imagined reduction might be more satisfactorily accomplished. The same ingenious gentleman has also proposed a forceps by which the extending power can be instantaneously disengaged,—a contrivance similar to which, I think, I have seen many years ago in the Glasgow Infirmary. Even the windlass cannot be deemed a new application here, for something of the same sort was part of Petit's machine for reducing luxations of the shoulder, as may be seen in the drawing at p. 192, vol. i. of Heister's Surgery.

Another plan, which is attended with less trouble than those above described, and also obviates the necessity for pulleys, consists in placing the patient on a couch or mattress upon his back, when the surgeon seats himself alongside, and places his foot, the boot or shoe being removed, in the patient's axilla: he then, with both hands, lays hold of the wrist, or a bandage previously fastened round the arm above the elbow, when, by pushing his heel upwards, and throwing his body backwards, the head of the bone may be made to glide into its proper place. I have known this plan succeed when others have failed, even though aided by the pulleys; and I believe that, if judiciously and energetically applied, few examples will be met with in which it will not answer. If necessary, additional power may be gained by passing a towel under the axilla, and desiring an assistant to pull upwards, whilst the surgeon increases the extending force, as he throws his body backwards, by having had, whilst in the sitting posture and slightly stooping, the band attached to the patient's arm fixed round his own shoulders. Figure 105 will convey a very distinct idea of the manner of this proceeding.

These are the methods of reducing dislocations of the shoulder-joint, which, in so far as I am aware, are most commonly in use; there are others, however, which some consider equally efficient, and for a description of which I must refer to the works of Paré, Scultetus, and Heister, or other systematic authorities of the last and preceding century. The ancient ambi, the scala, and the glossocoma, are now looked upon with interest only as relics of bygone ages. Although Bransby Cooper relates the case of a farmer near Norwich, who, being frequently the subject of luxation of the humerus into the axilla, used to "do the doctor," by balancing himself over a gate, his body on one side, his arm on the other, we no longer hear of patients being sus-
pended by the armpit over the upper bar of a ladder, or the top of a
door, nor hung from the ceiling by the wrist of the injured arm, with
the sanction of the modern surgeon. The latter practice was in high
estimation with Charles White, of Manchester, towards the end of the
18th century, and it has recently been revived in a modified form by
Malgaigne and Syme, who, however, keep the patient on his back on
the floor, and forcibly bring the arm upwards above the head. Though
the pathology of luxations in this joint is now better known than in
former times, the history of their treatment clearly shows, that it
would indeed be difficult to resort to any method which has not pre-
viously been tried and recommended. The surgeon will best display
his judgment, not by obstinately refusing to resort to any plan but
that which he may think best, but by attempting, after his first effort
has failed, any other which will give his patient a reasonable chance
of relief: if he fail with one, he may succeed with another; if gentle
force will not suffice, he must apply a greater amount; if a

Fig. 105.

steady extension will not answer, he must try the lever and
fulcrum; and, should one attitude of the arm not do, he may
place it in another; he may move it gently from side to side,
upwards and downwards, or twist and thrust it rudely in all direc-
tions to attain the wished-for result; and should he succeed, as
in all likelihood he may, he ought not on that account to imagine
that the successful plan in this instance, and that only, is the best for
all future cases.

It will be remarked, that no broad distinctions have been here drawn
between the methods to be pursued in one dislocation and another.
The means above recommended I have followed in my own practice,
and seen successfuly used by others, whatever might be the position
of the bone; and the references which have been made to other
measures now deemed obsolete, as well as the occasional necessity of
varying the plans and the attitude of the limb, will be sufficient to
show, that the surgeon must often trust more to his own skill and
mechanical ingenuity, than to any minute rules which might be given here, but which are purposely omitted, as not being in accordance with the arrangements of this work.

A most ingenious apparatus for reducing luxations and fractures has been brought under the notice of the profession in this country by Dr. G. O. Jarvis, of America. It can be fitted to either the upper or lower extremity, and possesses greater power in a smaller compass than any contrivance I have ever seen for surgical purposes. It consists of various pieces of metal, and the extending power is applied by means of a rack and pinion-wheel. It would serve no good purpose to describe it here, but the apparatus may be seen and had at Mr. Weiss's, to whose care Dr. Jarvis has committed it. A contrivance of a nearly similar kind has been constructed by Mr. Coxeter, at the suggestion of Mr. G. N. Epps, who has given a description of it in the Lancet for the 26th of July, 1845.

It may often be a question, whether or not, in dislocations of old standing, the surgeon should persist in, or even attempt, the application of violent force to effect reduction. I have seen a most excellent practitioner fail at the shoulder, after the lapse of three weeks, when another, making the attempt a few days afterwards, succeeded. I have myself failed in the fourth week, while again I have been successful on several occasions in the eleventh; and, though cases have been put to rights even after the third month, the propriety of interfering with the generality of such instances may admit of doubt. Frequent experience on the living subject, and that acquired in the dissecting-room, has sufficiently demonstrated the fact, that even when the head of a bone is left in its abnormal position, the limb below will gradually acquire an amazing latitude of movement, and a new joint will be formed, which, in many respects, almost equals in efficiency the natural articulation before the injury. I have seen individuals with old unreduced dislocations of the shoulder move the elbow backwards and forwards, and also raise the hand to the head, with the utmost facility; and every one experienced in the dissecting-room and in museums must be familiar with the admirable manner in which nature adjusts the newly opposed surfaces to each other. These observations are peculiarly applicable to the shoulder and hip-joints, but they should be kept in view in other regions also; I cannot imagine that they will engender carelessness either in the examination of any joint supposed to be the seat of displacement, or in the application of remedial measures; and I shall only, therefore, add the views entertained on the above important question by one of the greatest of all authorities on the subject, Sir Astley Cooper, who, in the preface to the posthumous edition of his work on Dislocations and Fractures (1842), has left behind him the following statement, grounded, it must be kept in mind, on an experience greater, perhaps, than ever fell to the lot of any other individual. "I feel," says he, "that my professional brethren will be disposed to think that I have limited to too short a period the attempts at reduction. It has been stated that dislocations have been reduced at four, and even six months after the injury; and
DISLOCATIONS OF THE SHOULDER-JOINT.

this assertion I am not disposed to deny; indeed, I have myself had an opportunity of witnessing examples of the fact; but, excepting in very exsanguinated, relaxed; and aged persons, I have observed that the injury done in extension has been greater than the advantage received from the reduction; and, therefore, in the case of a very strong, muscular person, I am not disposed, after three months, to recommend the attempt, finding that the use of the limb is not, when reduced, greater than that which it would have acquired in its dislocated state. Let this be fairly represented to the patient; and then, at his request only, the reduction should be attempted; but, 'with all appliances and means to boot,' the extension must be very gradually made, and without violence, to avoid injury to the muscles and nerves.”

It is customary to suppose that the head of the humerus cannot be luxated directly upwards; but I have long been of opinion that such an event, to a partial extent, may and indeed does occur pretty frequently. I have met with various examples in the dissecting-rooms, in which the end of the bone has been in close contact with the acromion process and spine of the scapula, or with the coraco-acromial ligament,—lying, in the one instance, a little above and behind the upper part of the glenoid cavity; in the other, somewhat above, and in front, between the natural articular surface and the coracoid process; both, however, coming strictly under the title of partial luxation upwards. Whether these effects were the result of immediate violence or of gradual change, I cannot decide: the capsular ligament seemed entire, but elongated, in some of the examples, whilst in others the articular surface of the humerus was in contact with the parts above, the capsular ligament being attached to the surrounding textures, which, thickened and infiltrated with lymph, bore all the marks of former inflammation. The occurrence of the rupture of the tendon of the long head of the biceps has been noticed by Mr. Stanley, Dr. Knox, and others; and Mr. John Soden, jun., of Bath, has related (Trans. Med. and Chir. Soc., 1841) the particulars of a case of supposed sprain in the shoulder, which dissection afterwards proved to be a partial displacement of the humerus upwards, and luxation of this tendon forwards on the lesser tuberosity. That this tendon is displaced in the luxations forwards or backwards (or perhaps, to speak more correctly, that the head of the bone in such instances is displaced from the tendon), there can be little doubt: I have seen the change more than once in the dissecting-room. In some I have found the tendon partially torn and elongated, lying either in the natural groove, or in a new one formed by friction; in others I have observed the tendon torn across about an inch from its upper extremity, which floated free within the capsule, whilst the other end was adherent to the groove between the tuberosities. In some of these, old unreduced dislocations existed; in others, every mark bore evidence that this injury had at one time occurred. There is now in my collection in the museum of King's College, a preparation strongly corroborative of the above observations. On a subject, I noticed that one shoulder was more prominent than the other; and in the progress
of the dissection the head of the humerus was found lying immediately under the deltoid muscle, in contact with the acromion, and surrounded by a very thin capsule of cellular texture. On raising the head of the bone, it was ascertained that the long tendon of the biceps was torn, the under end being adherent in its natural groove, and that, in addition, a dislocation of the head of the humerus (forwards in all probability) had been in a manner reduced; but, instead of passing again into the capsule, had been thrust between this texture and the deltoid muscle. Only a small portion of the glenoid cavity was visible at its lowermost point, the greater part being covered by the flattened capsule. Doubtless, in this case, the original opening in the ligament had been only sufficient to let the head of the bone escape, and not free enough to permit of proper reduction. Such an occurrence I believe to be exceedingly rare, almost all evidence going to prove that the capsular ligament is in general so extensively torn open, that the head of the bone cannot possibly be obstructed by it in its backward course: yet the preparation confirms the observation of Delpech, who, though he suspected such an occurrence, had himself met with no anatomical proof of the fact.

I have seen in practice several examples of supposed rupture of the tendon of the biceps, attended with the usual symptoms of severe sprains of the shoulder-joint; but cannot say that I was ever convinced of the reality of the injury. The knowledge that such a rupture may occur, however, accompanied or not with luxation of the bone; that the entire tendon may leave its groove; that the capsular ligament may lie behind the bone, after reduction has been supposed to be completed, must be of considerable practical consequence, as the surgeon may thereby explain the cause of certain conditions of the shoulder resulting from injuries of this most important articulation, whether the latter have been palpable or obscure in character.

I have already stated (p. 218), that the circumflex nerve, as it passes behind the neck of the humerus, has been found both stretched and torn in different cases, when the head of the bone has been driven deep into the axilla; and these facts sufficiently account for the loss of power, and decay in bulk, of the deltoid. In some instances, it is easy to understand that the nerve may regain its functions after being merely overstretched; whilst in others, the same event may happen, but more slowly; after union of the divided parts,—a fortunate occurrence, which I imagine must happen but rarely. Loss of power in the deltoid is not, however, a common sequence of simple luxations.

Compound dislocation of the shoulder is rarely met with in practice. The extensive and perhaps complete separation of the soft parts from the head of the bone will permit most speedy and simple reduction; but in some examples the injury may seem so great, that, instead of attempting to save the arm, it will be better to amputate at the joint. I do not suppose that it can ever be requisite to remove a portion of the humerus to facilitate reduction: were such a question mooted, I should most incline to enlarge the wound in the integuments. Were
the head of the bone injured at the same time, excision might then be
the best practice, provided it was still determined to give the limb a
chance. I have seen one example of compound luxation of this joint.
It was occasioned by a large water-wheel, which, in revolving, came
in contact with the arm, caused a rent through the deltoïd and skin,
and thrust the end of the humerus prominently outwards. The patient,
though stunned, was not seriously injured elsewhere; yet it was
thought advisable to amputate. The state of shock continued for
several hours; and the operation, partly on this account, and also to
give time to procure instruments, was delayed till next morning.
Meanwhile the head of the bone was replaced, which was easily done,
and the edges of the wound were brought together. When the surgeons
met again, the man seemed in such a favourable state, and the parts
looked so well, that it was wisely resolved not to use the knife. The
wound closed without a bad symptom, a slight synovial discharge con-
tinued for about three weeks, and some months after I saw this indi-
vidual in excellent health, and already able to make a tolerable use of the
injured arm.

I feel that I ought not to quit the subject of luxations of the shoulder-
joint without referring the reader to the edition of the well-known work of
Sir Astley Cooper, which was issued under the valuable superintendence
of Mr. Bransby Cooper, and which, in the present state of our knowledge,
leaves but a narrow field for further observation.

Dislocation of the clavicle may occur either at one extremity or the
other. When at the outer end, a projection may be felt and seen on the
upper surface of the acromion process. This displacement, in ordinary
cases, is seldom to great extent, the ligaments between the clavicle and coracoid process apparently pre-
venting it. I have known such an injury mistaken for dislocation of
the shoulder. The sternal extremity may be thrown either in front
of the upper part of the sternum, or, in other cases, somewhat backwards
and upwards. Such accidents upon the whole are of rare occurrence, as
force is more generally productive of fractures of this bone. In luxation
of the outer extremity, which is most frequent of the two, and is here
exhibited in figure 106, the parts may readily be put in their natural
position by drawing the scapula outwards by a figure-of-eight between
the scapula behind the shoulders, and pressing the head of the clavicle
down with the finger or thumb, when an attempt may be made to keep
the end of the bone in its proper position by means of a pad in the
axilla, and one on the outer extremity of the clavicle, which must be
covered by turns of the roller, so as to assist in fixing them in their proper situation. These means, however, although combined with keeping the arm steady in a sling, will in all likelihood not have the desired effect: and, moreover, the pain which the injury occasions, is not so great as to induce the patient to submit to the irksomeness of a continued application of such an apparatus. Unless the displacement be considerable, I believe it will be the best plan in most instances to leave the shoulder alone, and merely to keep the fore-arm in a sling.

Cut 107 exhibits the most common displacement of the inner end of the clavicle; the end, however, may be more in front of the sternum. The figure-of-eight above described may be applied, and a pad placed over, should the case require it. Here also it is extremely difficult to keep the extremity in its proper seat. A false joint will most probably be the result, and fortunately in this instance, as in the preceding, the condition is productive of no serious inconvenience.

I once saw a case of displacement of the inner extremity of this bone in a newly-born infant, which had happened during birth. The end rested in front of the sternum, and could be pushed into its proper place with great ease; but, when left alone, it immediately slipped out again. Nothing was done, a new joint formed, and the child afterwards possessed as much power in the one arm as in the other.

Sir Astley Cooper refers to a case of displacement of this part of the bone backwards, which occurred to Mr. Davie, of Bungay, in Suffolk, wherein that gentleman successfully removed about an inch of its extremity to relieve the patient of dysphagia, occasioned by pressure upon the oesophagus. The displacement had occurred gradually in consequence of great spinal deformity; and Sir Astley states that he had never seen an instance of the luxation resulting from violence, although he admits its possibility.

Several cases of this dislocation, occasioned by violence, have been observed since Sir Astley Cooper's work was first published; and I may refer the reader to the London and Edinburgh Monthly Journal of Medical Science for October 1841, for some interesting notices of examples of the kind.

Displacement of the upper margin of the latissimus dorsi muscle, beneath the lower angle of the scapula, has been referred to occasionally. I have not seen an instance of the kind on the living body. It is quite possible, however, judging from appearance on dissection, that such an occurrence may happen; but I should suppose that a slight movement of the arm and scapula would put all right again.
CHAPTER III.

FRACTURES.

Fractures of the bones of the hand and fore-arm are of common occurrence. In all instances where amputation is not requisite, there is little trouble in replacing the fragments or in keeping them in proper position.

In fractures of the phalanges it is occasionally difficult to detect the nature of the case. In such examples the fragments are not displaced, and there is scarcely any necessity for apparatus, as the pain which the patient suffers, on any considerable motion of the part, will induce him to keep it sufficiently steady. When there is displacement, a slight extension will suffice to put the fragments into apposition; and a little slip of pasteboard or gutta percha in front or behind, kept on by a bandage, or by a few turns with a narrow strip of adhesive plaster, will constitute all the apparatus required. If the phalanx connected with the metacarpal bone happens to be the one under treatment, it will be most satisfactory to prevent all motion of the joint above; and this may be done by carrying the splint along the palm of the hand, and fixing it by a few turns of a roller, broader than that used for the finger. Perhaps in such a case the best plan would be to place a flat splint upon the hand and finger so as to steady all.

The metacarpal bones when broken are seldom much displaced, and there can be no difficulty either in detecting such injuries or in setting the fragments. There is no need of a splint (except when the destruction of the soft parts has been considerable), as the neighbouring entire bones will answer the same end. However, should one be deemed necessary, a piece of pasteboard, about the breadth of the hand, should be placed on the palm, and fixed there by plaster and bandage. The splint should extend a little above the wrist, and as far down on the fingers as to allow them to rest upon it; by such means the most perfect quietude will be insured.

When the bones of the carpus are broken, the injury generally endangers the safety of the hand, for violence sufficient to cause such fractures is likely to produce great destruction of the soft parts. Should amputation not be deemed necessary, a splint of pasteboard must be applied in front, so as to prevent all movement. As little force as possible should be used in putting or keeping the fragments together, and every effort made to moderate the inflammation consequent to the injury.

The bones of the fore-arm are often broken, either singly or conjointly, and the radius is most frequently the seat of injury. This bone generally gives way, in consequence of a fall, when the hand is thrown out to support the body; it may, however, be fractured by a blow, or a weight coming upon it. It is seldom broken in its upper portion, compared with the frequency of the accident in the middle or
lower part, more particularly in the latter; and here, when the injury is occasioned by the weight of the body being transmitted through the bone, the fracture is often comminuted, the fragments being separated longitudinally as well as transversely. The accompanying figure (108) exhibits a fracture of this bone, in a situation where it is by no means uncommon. The lower fragment is represented as leaning towards the ulna, the pronator quadratus being usually considered the cause of this approximation; but in general all fractures in the fore-arm evince this disposition, the fragments inclining more to the mesial line than towards the surface.

In most cases the injury is not difficult to detect, especially when about the situation displayed in the sketch; occasionally, however, in the lower part, when the fracture is about an inch, or a little more, above the carpus, the difficulty is extreme, in consequence of the swelling which follows the injury, as also a certain amount of impaction, and the pain attending the examination. Of late years it has become the custom to call this "Colles's fracture," after the name of the distinguished Dublin surgeon. Usually there is considerable distortion, and there may be such depression of the ends of the fragments upon the ulna that the injury may resemble luxation of the hand and carpus towards the radial margin of the arm. In such a case, too, the lower end of the ulna will be so prominent that a mistake may be made by taking this as the principal feature of the injury, while again the fulness in front a little above the annular ligament may excite suspicion of luxation of the hand backwards. These conditions are tolerably well marked on this drawing (fig. 109), taken from a cast in

the museum at King's College. It may be well to bear in mind that distortion like this may possibly occur some time after the bones have seemingly been well set and firmly united. Some years ago a patient, with his arm resembling this drawing, brought an action against the surgeon who had treated him some months before, for a fracture such
FRACTURES OF THE FORE-ARM. 231

as above described. It was proved, that when the splints were taken off the fore-arm was straight, and that in all probability the man brought on the distortion by resuming his work as a carpenter before the junction had been sufficiently firm to resist the influence of the muscular action. In a suspicious ease (that is, when from the pain, particularly during attempts at pronation or supination, and swelling, combined with the nature of the violence, there is every probability that the ease is actually one of fracture), as the severity of the injury will render the part useless for weeks to come, the best practice will be to treat it as such, but it will be advisable to explain matters to the patient, lest some other practitioner, by applying more force, or perhaps having a more favourable opportunity for examination, detects a fracture, and so lays the first party open to the suspicion of carelessness or incompetency. In such an instance, then, and of course where the fracture is distinct, the hand must be brought and kept on a line with the long axis of the fore-arm, for in this attitude the fragments can be best adjusted, and a splint of wood or pasteboard, or other suitable material, about ten inches in length and two in breadth, or of length and breadth proportioned to the size of the part, should be applied on the anterior surface of the fore-arm and hand; another should be placed behind, and both retained by a common roller. In about three weeks, or as soon as the fragments seem to have united, the wrist-joint should be gently moved and rubbed, to obviate the stiffness which is likely to remain.

In applying these splints, it is customary to put a piece of lint between them and the skin, to prevent injury from the contact of the hard substance. If pasteboard be used it may either be wetted in tepid water, or not, previous to application; I think this of little consequence; but, whenever it is done, care should be taken that it is not too much softened, lest, under the supposed security of the splint, displacement occur again ere the material hardens and assumes a permanent form. In the present day gutta-percha, or sole-leather, is frequently used for such splints, and by means of warm water they can be moulded to any required shape or size.

The ulna may be broken at any part of its course. Figure 110 exhibits the fissure where fracture is common. It may be lower, however; but the additional strength higher up gives considerable security to this part of the shaft. Here, as with the radius, the fragments may lean to the opposite bone; and I must therefore beg attention to my remarks in reference to the treatment of fracture in both bones. A fall or blow will probably be the cause of such a fracture. I once treated an instance of the latter kind, about three inches above the carpus, which was occasioned by the patient, in striking downwards, hitting the back of a chair, not being aware of its presence.

The treatment differs in no respect from that of similar accidents in the radius. When the olecranon process, however, is broken, the case is more serious; for, in addition to the fracture, there is an injury of the joint. In an instance of this kind I once found it necessary to
perform excision of the ends of the bones of this articulation, in consequence of inflammation and caries resulting from the primary injury. Such events are, fortunately, by no means of common occurrence; but non-union of the fragments may be the result, and a partial loss of power with the triceps extensor, as may be imagined from a specimen of this kind (fig. 111), which shows the distance the process may be separated by the action of the triceps. In order to prevent such a result, the arm must be kept extended, so as to have the fragments as nearly in contact as circumstances will permit. A splint, ten or twelve inches in length, in front of the elbow, will answer this purpose.

Fig. 110. Fig. 111. Fig. 112. Fig. 113.

Here it will be proper to bear in mind the possibility of a stiff joint; for if there be a likelihood of this result, it may be best to put the elbow in a bent position, as the patient will have more use of the arm in this attitude than in a state of extension.

Both bones of the fore-arm may be fractured at the same time, and the fissures may be almost opposite to each other, as represented in either of these sketches (figs. 112 and 113), or one bone may be broken in its upper third, another in its lower. When the injuries are towards the middle of the fore-arm, as exhibited in the first of these cuts, and possibly, too, when higher up, there may be some difficulty in making sure that both are broken; but if a little above the wrist, as in figure 113, the mobility, as well as other circumstances, will leave no doubt about the nature of the accident.

The treatment of these injuries will not, in general, differ from that in fracture of a single bone. In the latter case, when there is no great
tendency to displacement, a single splint may probably be found sufficient; here, however, two should always be used, and in adjusting them, one in front, the other behind, it must be remembered that the four fragments, if allowed to be close to each other, may coalesce by callus, and thus the movements of supination and pronation will be lost. If proper care is bestowed in adjusting the splints and bandages, the muscular cushion on each surface of the interosseal membrane will be so kept between the bones, that such a misfortune can scarcely happen. This caution should not be overlooked even in the case of fracture of one bone only; and in most instances, particularly when the fore-arm is thin and flat, it will be a wise precaution to lay a pad along each surface before the splints are applied. If the fractures are near the elbow, they may be treated much in the manner recommended for those in the lower end of the humerus.

Compound fractures are by no means unusual in the fore-arm, but unless the injury be otherwise severe, such cases generally do well. Sometimes everything will go on as in simple fractures, at other times there may be diffuse inflammation, suppuration, necrosis, and the usual train of misfortunes resulting from compound fractures elsewhere; but even in most unfavourable-looking cases the surgeon should never resort to amputation while there is the slightest hope of saving the hand; for, however unwieldy the part, it will assuredly be better than any substitute. In such cases the pads, splints, and bandages will not require to be materially different from those which are used in other instances, although it may be requisite to adjust them so that proper care can be taken of the external wounds.

Some years ago I had under my care in King's College Hospital, a case which admirably illustrates the advantages of what is now so generally called conservative surgery. A boy, seven years of age, was brought at the hour of visit, with his hand and fore-arm fearfully lacerated, in consequence of having been drawn between the eogs of the large and small wheels of a street-sweeping machine; the bones were shattered in countless places, and here and there the fragments were exposed through some of the numerous wounds and gaps on the surface. The parts seemed as if they had been forcibly compressed and lacerated between a couple of gridirons. All the important vessels, nerves, and tendons seemed entire, however, and I resolved that an attempt should be made to save the extremity. The case was attended to with the utmost care by the house-surgeon, Mr. Cockburn, and the result was most satisfactory. Every joint was preserved; flexion and extension were perfect at the elbow, wrist, and fingers, supination and pronation being also readily performed.

The formation of a false joint may follow such injuries (simple or compound) as those under consideration, and this drawing (fig. 114), taken from a preparation in King's College, gives a good example of the kind after a double fracture, in which the fragments of the radius are united, and those of the ulna, opposed to each other by smooth, callous-looking surfaces, surrounded by slight exudation of new bone. Such a condition may or may not be accompanied by great incon-
venience; and if it is thought proper to interfere, the methods recommended in the chapter of False Joints, will afford the best chances of success; but more will be found on this subject in the chapter on Incisions in the Upper Extremity.

Occasionally in young subjects (before puberty) one or both of these bones will bend before breaking. Perhaps all bones do so, more or less, before fissure occurs; but the condition to which I allude is sometimes remarkably conspicuous. This sketch (fig. 115) of a young radius (as may be seen by the epiphysis below having separated) in the Museum at King's College, gives a good illustration of the probable state of the bone in such cases: at first there may only be a bend; but as the force is continued, the convex part gives way, and at last, according to the friability, the whole thickness will suffer. The figure represents, at one part, bending and fracture combined, and towards the lower extremity a slight indentation and curve may be observed. It may not be deemed a scientific analogy to compare this radius with a walking-stick in a similar condition, yet there is, in many respects, great resemblance; and any one who has examined such accidents on the living body will agree with me in thinking so. In several instances which I have met with in practice, the distortion has been well marked, but crepitus has not been by any considerable force has been required to straighten the fore-arm, and a splint has appeared less necessary than in ordinary fracture, although I have always deemed it best to apply one. The setting of the fragments has forcibly reminded me of earlier days, when, by an unlucky "cast" my fishing-rod had suffered in a somewhat similar manner. It seems to me singular that such an injury of bone should have been in a manner overlooked by former surgeons — for it is doubtful if it was familiarly known until the present century. Dr. Norris has alluded particularly to this subject, and has referred especially to Dr. J. R. Barton, and to Jurine, of Geneva, as excellent authorities regarding it. The latter gentleman had seen about twenty cases of the kind during a practice of fifty years. I imagine that there is scarcely a bone in the body in which it may not occur, and, in my opinion, it is far from unusual in the ribs.

In all severe fractures of the hand and fore-arm it will be best, if not absolutely necessary, to confine the patient to bed at first, where the part can be conveniently placed
on a pillow, with the hand on a level with the elbow, or even a little higher; and when he sits up or moves about, the extremity should be bent at the elbow, and kept in a sling, until the person feels that he can dispense with such an apparatus. A bandage passed round the wrist and neck, as exhibited in figure 119, may be used on such occasions, or a leather case, with suitable straps, may be preferred: but in general a handkerchief-sling answers admirably.

Fracture of the lower part of the humerus is of more frequent occurrence than that of the upper portion of the forearm. The bone may be broken in its shaft, as exhibited in this cut (fig. 116), the articular surfaces may be separated, or a condyle may be broken off. One of these injuries may happen by itself, or all may be combined, as was the case in the example from which this sketch was taken. In the shaft there will be no difficulty in detecting the nature of the injury, and very little extending force will be sufficient to replace the fragments; in the condyles the swelling will often cause difficulty in the diagnosis, but the displacement is seldom great, and slight pressure with a bandage serves to keep the fragments in apposition: in both instances an apparatus similar to that represented in figure 117 will be requisite. A piece of pasteboard, gutta-percha, or strong bend-leather, of the shape similar to that shadowed in the figure, should be applied on one surface of the elbow, another of a like kind on the opposite, and both should be retained with a bandage, which should extend as here exhibited, from the hand to the middle of the arm. The splint for the inner side should have a round hole or deep hollow opposite the condyle, so that it may fit without injurious pressure. Sometimes if bandages are thus applied it will be found that the fingers become edematous, when they also must be enveloped in narrow rollers. In many instances the swelling around the elbow will be so great, that it will be impossible at first to draw the bandage so tight as it is represented in the sketch; indeed, a good deal must be left to the discretion of the practitioner:—often it will be necessary to temporize
until inflammation has subsided; and although I have mentioned pasteboard, gutta-percha, and leather splints, these will sometimes be found not sufficiently strong, and wooden ones, or those of iron, tinned or japanned, will sometimes be preferable. Occasionally, when the condyles only are implicated, a bandage alone will keep the fragments in apposition.

In a case which I saw lately, although the external condyle was quite moveable, no apparatus was applied, on the supposition that the patient could not survive the other injuries he had sustained (which he, nevertheless, did for a month), I found on post-mortem examination that the bone had been fractured immediately above the condyles, and that a fissure extended through the articular surface into the joint; yet the fragments had united as favourably as if every possible care had been taken of them by means of apparatus.

Some years ago I had, in King's College Hospital, a case of compound fracture immediately above the condyles. A small wound on the skin seemed to communicate with the joint, and severe inflammation and suppuration ensued. The arm, nevertheless, did well, though I found it requisite, about a month after the receipt of the injury, to remove by incision a portion of the external condyle which had become necrosed. In all fractures in this situation, or in the upper part of the fore-arm, I should strongly recommend (as in regard to luxations of the elbow), the bent position at first, and that after the lapse of three weeks or a month gentle movements should be commenced, to obviate stiffness, which is very apt to follow such injuries.

Fracture may occur in any part of the humerus above the line exhibited in figure 116; indeed this bone suffers more frequently about its middle than elsewhere, and the nature of the injury may in general be most readily detected; the swelling and distortion of the arm, its diminished length, should the fragments ride over each other, its mobility, and the crepitis, will all be distinct. The dark line in the drawing (fig. 118) exhibits a common seat of fracture in the upper end of this bone, where, I believe, it is most frequently seen in persons advanced in years. Whether the fracture be lower down than the insertions of the muscles which form the anterior and posterior boundaries of the axilla,—a little higher between these muscles and the tuberosities in the surgical neck, or between these prominences and the head,—in the anatomical neck, as it is called,—the treatment should be the same. The lower fragment being sufficiently drawn down, with its upper end kept in natural place by a pad in the axilla, a splint, about two inches and a half broad, and long enough to reach from the elbow to the acromion, should be laid on the outside of the arm, and both should be retained by means of a roller, which should be first carried
round the limb and then round the chest, as represented in figure 119. The bandage round the chest keeps the parts steady by fixing the shoulder, and the pad in the axilla answers the double purpose of preventing displacement of either fragment inwards; for if the fissure is above the insertions of the latissimus dorsi and pectoralis muscles the lower fragment may be drawn towards the side by their action, and if below their insertion, the upper fragment may be drawn in a similar direction by the same influence. There is great trouble in retaining a bandage round the chest in a proper position for any considerable length of time, such as may be required in the instance of fracture at present under consideration; it must, therefore, be put right from time to time. A deal of trouble may be avoided in these fractures, and in many others, on which it is necessary to retain a bandage for a long period, by moistening the calico with a thick solution of starch, or dextrine, at the time it is put on, which, when dry, causes the turns of the roller to adhere firmly to each other, and prevents their being displaced either by the movements of the patient or the contact of the usual coverings in the way of dress. To prevent oedema the hand and fore-arm should be enveloped in a bandage. The limb, as in all other serious injuries of the superior extremity, must be worn in any convenient sling, such as those previously alluded to in the chapter on Luxations.

A complicated kind of injury sometimes happens at the shoulder, viz., dislocation of the head of the humerus into the axilla, and fracture in its neck, of which I have seen some well-marked instances, admitting no possible doubt regarding their nature. In such cases attempts should be made to thrust the head of the bone into its proper place:—the thumb or fingers may be used for this purpose; or, as was proposed by Delpech, a tourniquet may be applied, the acromion being the fixed point. If this cannot be done (and even if it can), the arm must be put up as if for a simple fracture in the neck of the humerus; and whatever be the result, no attempt need be made in future to reduce the luxation, as it will not succeed, and may do much harm. In the examples above referred to, a false joint formed between the shaft of the humerus and the glenoid cavity, and the head of the bone could be distinctly felt fixed on the lower margin of the scapula during the ordinary and, of course, somewhat limited movements of the arm. This injury has often induced me to ask the question, how the head of the bone, being fairly separated from the shaft above the tuberosities, and therefore in all likelihood within the capsular ligament, had con-
tinued to survive. Doubtless, some portions of capsule or periosteum had still kept up a vascular connexion, but the separation between the head of the bone and the shaft was so great in the instance to which I allude, that it was difficult to imagine that any bond of union had been left when the injury happened, and possibly the part may have been merely enveloped in a newly-formed cellular capsule.

Although I have recommended the use of pads and bandages in these cases of fracture in the neck of the humerus, I am of opinion that in some instances the surgeon may dispense with them. Persons advanced in life seem most liable to such fractures, and most of the examples which have come under my notice have been in females, on whom there is difficulty in adjusting any apparatus. I am doubtful, if in aged persons, who may probably not require much active or vigorous use of the arm, whether as much advantage will result as will compensate for the necessary annoyance and restraint of such treatment. Some time ago I saw a case of fracture in the surgical neck of the humerus in an old woman, at King's College Hospital, in whom the pad in the axilla and bandage occasioned alarming oedema in the hand and fore-arm, and otherwise caused both patient and all of us much trouble. Finding that there was no disposition to much displacement, I removed all the trappings, and let her keep the extremity in that position she found most agreeable. This proceeding added greatly to her comfort, for she was bedridden with a fracture in the upper part of the thigh, which befel her at the same time. In three weeks union seemed to have taken place, and she made some use of the arm. Some weeks afterwards this patient died, and on dissecting the shoulder I found the fragments firmly united in most excellent apposition. An instance came under my notice of a fracture of this kind, which had for a few days been overlooked and neglected, suppuration occurred, a large abscess formed in the axilla, inflammation extended to the shoulder-joint, the upper end of the humerus—the upper fragment—became necrosed, and the patient, an old man about seventy, died from exhaustion.

The scapula is occasionally the seat of fracture. The glenoid cavity may be broken into various fragments,—a rare kind of injury, of which, however, there is an excellent specimen at Netley, as represented in this drawing (fig. 120). I should doubt if it would be possible on the living body to discover the nature of such an injury.

Sometimes the glenoid cavity is separated from the body of the scapula in one or other of the lines indicated in figure 121. I imagine that I have seen a case where the fissure passed in the line nearest the articular surface, but it is probable that it occurs most frequently in the course of the other line, for in the dropping of the shoulder, which is one of the characteristics of this injury, the coracoid process has been observed to sink at the same time. In such a fracture the patient may have fallen, or have received a severe blow on the shoulder. The absence of all characteristic marks of dislocation at the joint, the humerus being distinctly felt through its whole course, and, when rotated, ascertained to be sound, the slight subsi-
Fractures of the Scapula.

dence of the head of this bone, the inability to move the arm without great pain, more particularly when it is twisted backwards, and the

Fig. 120. Fig. 121.

presence of crepitus when the arm is raised and pushed towards the scapula, all conduce to the suspicion of the nature of the case. The treatment may be similar to that for fracture of the upper end of the humerus, great care being taken to keep the arm well supported in a sling.

I have known an instance where the coracoid process of this bone was broken, and drawn downwards by the combined action of the pectoralis minor, coraco-brachialis, and biceps muscles; nothing could be done to keep the process in its natural position. Fig. 122 gives an example of this kind. The moveable fragment would probably be more displaced than is here represented, especially if the pectoralis minor muscle should happen, as is shown in the drawing, to be attached lower than the second rib. Mr. South has related (22nd vol. of Med. Chirurg. Trans.) the particulars of a fracture of this kind, which was accompanied with separation of the acromion and partial luxation of the head of the humerus forwards. The injury to the process was not detected until the death of the patient, which occurred some few
days after the accident. An example where the whole process was broken off occurred in the practice of Mr. Arnott, at the Middlesex Hospital. In this case, too, an early inspection was permitted by the death of the patient, and it was found that an abscess had formed in the seat of fracture.

The acromion process may be broken, but the accident is of rare occurrence. Mobility of the part after a blow or fall upon it, and perhaps a slight elevation at the seat of fracture with marks of contusion and indistinct crepitation might indicate the nature of the injury. I have dissected a number of examples of apparent fracture of the end of this process; but in such instances it is doubtful if the movable portion had ever been fixed to the rest of the bone. Whilst the acromion may be said to prevent extensive dislocation of the head of the humerus upwards, the round end of this bone may, in like manner, be deemed a preventive to any part of the process being driven downwards. This may probably be the reason why the acromion is so seldom broken. Suspending the arm in a sling will be the principal feature of the treatment.

The body of the scapula may be split in any direction; the fissure is usually transverse, and below the spine: the fracture is somewhat rare; it is commonly the result of a fall upon some angular body, such as the margin of a table, or it may follow a blow with some heavy object like a brick-bat; it is sometimes difficult to detect, as the fragments are seldom very moveable; but there is nothing in its nature or treatment calling for particular comment here. The various lines in the drawing (fig. 123) will point out the ordinary position of some of the fissures here referred to. A flannel roller round the chest usually constitutes the mechanical appliance.

The clavicle is often the seat of fracture, being generally broken about its middle, though either extremity may suffer. The bone may be broken into two portions only, or into several more; a fall, or weight coming on the shoulder, being the most common cause of the injury. The nature of the case can be made out by the sight alone in many instances, but the application of the fingers will put the matter beyond doubt. When there is much displacement, the outer extremity of the inner fragment will invariably be felt over the other portion of the bone, immediately under the skin, as may be imagined from the accompanying design (fig. 124). The fragment is elevated by the clavicular portion of the sterno-mastoid muscle, while the weight of the shoulder carries the other downwards. There is often much contusion and swelling in such cases, and occasionally (though rarely) the fracture is compound.
In an ordinary case the arm should be put up in this way:—
A large pad, of tow, hair, or other convenient material, should be placed in the axilla, whilst the limb is drawn upwards and backwards: a few turns of the roller should then be passed over the shoulder and under the pad, so as to retain the latter in its position; the arm should then be applied close to the side, and fixed with numerous turns of the roller round the chest, as exemplified in fig. 119. The starch, as already recommended, will be of great service if used in this case. If the fracture be compound, the bandages must be so applied that a space shall be left uncovered in the site of the wound on the surface.

Two padded belts, one passing round each shoulder, drawn towards each other behind, between the scapula, so as to keep the shoulders well back, will answer well for this fracture. Mr. Simpson, of the Strand, with the sanction of Mr. Hancock, added a kind of sleeve to this apparatus, which, besides containing the arm on the injured side, is sufficiently long to pass round the patient's body and over his opposite shoulder in such a way as to keep the injured member perfectly quiet, and as if it were in a sling. A figure of 8, as shown in cut 125, made behind from shoulder to shoulder, will serve the same purpose as the above plan, and indeed, whichever is adopted, the fore-arm must be carried in a sling until the fragments have united.

I once had occasion to remove various portions of this bone, which had become necrosed in consequence of neglected treatment. The patient, a fine young man about twenty years of age, had the right collar bone broken by the falling of a tree; not being aware of the nature of the injury, he worked as a reaper for several hours after, until obliged to desist from excessive pain: violent inflammation, suppuration, and necrosis followed; but after the dead pieces were removed, he made a rapid and excellent recovery.

Fractures of the clavicle will often cause greater trouble than those
which are considered of a more serious character, and the utmost pains will not, on all occasions, suffice to prevent a slight prominence of the inner fragment. Fortunately, however, this condition is productive of no future inconvenience. In very stout muscular men I have had reason to suppose that a bandage or any other sort of apparatus was productive of no benefit, the weight of the arm and shoulder being such as to baffle all ordinary means of treatment. In such a case, as well as in others, I have seen a good cure after merely keeping the arm slung in a handkerchief.

CHAPTER IV.

LIGATURE OF ARTERIES.

The arteries of the hand are liable to injury, and the aid of the surgeon is generally necessary to suppress the hemorrhage. If the ends of the divided vessels can be laid hold of, no doubt the best practice will be to apply ligatures around them, and to facilitate such a proceeding the external wound may even be cautiously enlarged. The surgeon, however, has not always this in his power, and he must, therefore, suit his measures to the circumstances of the case. Thus in a wound of the palm of the hand, where it may not be practicable, with propriety, to search for the bleeding vessel, if pressure applied on the site of the hemorrhage, and on the principal arteries leading to the hand will not suffice, the chief artery passing to the seat of injury should be secured. Here it has been proposed to expose one of the principal arteries in the palm—the ulnar or its superficial arch, for example; but I imagine that smacks more of dissecting-room surgery than of ordinary practice, and I beg to call particular attention in such cases to a method which I have adopted with great success—that of passing a needle, or two or three if required, through the site of the wounded vessels, and tying thread tightly over to keep up compression.

Ligature of the radial artery may be done in any part of the course of the vessel. It can be readily got, in the dead subject, between the first and second extensor of the thumb, by making an incision between them about an inch in length, over the trapezium, and nearly parallel with the long axis of the radius, but on the living body the swelling of the parts may be so great as to preclude such an operation, or, at all events, to render it more painful and tedious than the occasion demands; indeed, under most circumstances, I would recommend that the vessel should be at once exposed a little higher up, in front of the forearm. The most eligible part for securing it in this situation will be about two or three inches above the wrist, where the pulsations can be readily felt through the skin. The forearm being placed in a supine position, on a firm table, an incision should be made through
the integument, two inches in length, about half an inch on the radial margin of the tendon of the flexor carpi radialis, and the vessel will be speedily exposed, after the division of the aponeurosis and the separation of a little cellular texture which lies in close contact with it and the two accompanying veins. Should it not be convenient to operate so low down, the artery may be secured in the upper third of the fore-arm, where it lies between the supinator longus and the pronator teres: an incision of the length above recommended, or perhaps a little longer, as indicated in the next figure (126), should be made, and in both instances two small veins will be found in contact with the artery. Such a proceeding is rarely called for, and would, I doubt not, be attended with greater difficulty than the operation lower down in the fore-arm.

If the wound be on the ulnar side of the hand, the ulnar artery should first be tied, or it may be necessary to secure it after ligature of the radial. The situation of the wound, as well as a little pressure on the main artery leading towards it, may give an idea which vessel it will be best to secure. If the ulnar is to be operated on, the best part for securing it is about two inches above the wrist, where it will be found accompanied by two veins between the flexor carpi ulnaris and the flexor sublimis: the nerve will be on its ulnar side. The vessel is more deeply seated than the radial; yet, if the parts be in a healthy condition, the operation should be easily accomplished. I have known a surgeon make a transverse incision, so as to cut the vessel across by way of discovering it; but this practice is not to be recommended. If this vessel cannot be secured at some point below the junction of the flexor carpi ulnaris and the flexor sublimis, it will be better at once to secure the humeral, than to cut into the fleshy mass at the upper part of the fore-arm; for, although the ulnar artery can be readily exposed by a good anatomist in this situation on the dead body, the wound would be so deep, the division of muscles so extensive, and the probability of great trouble being experienced during the process so likely, that I cannot recommend such an operation on the living, although it has received the high sanction of Marjolin, who once tied it in this situation.

Operations have been proposed upon the interosseal arteries, and Dr. Pancoast, of Philadelphia, has placed a ligature on the anterior one in an instance where bleeding continued after deligation of the radial and ulnar. Considering the depth of this vessel, I should imagine that there would be far greater danger to the arm by such an operation than if the humeral were exposed and tied.

It may happen that, for wounds such as those above referred to, as well as for other circumstances, the surgeon may deem it at once requisite to put a ligature round the humeral artery, or (as has happened in consequence of the anastomoses between the interosseal arteries and those of the lower part of the fore-arm, or in the hand, still keeping up the hemorrhage), he may find such a proceeding necessary, after having secured both the radial and ulnar. The operation will be best accomplished in the lower-third of the arm, where an incision
about three inches long should be made through the skin and intervening textures, along the inner margin of the biceps. The vessel is accompanied by two veins in this situation, and it may happen to have the basilic in front, either above or below the fascia. This vessel, if it be at all in the way, should be held aside with a blunt hook, and the same should be done with the internal cutaneous nerve, or any of the smaller twigs that may be met with, and seem in danger of being divided, though, in my opinion, little trouble need be taken about the latter. The median nerve will lie on the inner or ulnar margin of the vessel; it may, however, be fairly over, or, as sometimes happens, behind the artery, of which irregularity I have met with various examples. I have known this nerve tied instead of the artery; but the surgeon speedily discovered the mistake, removed the ligature, and placed it on the vessel.

The anatomist will here remember also that there may be a high division of the humeral artery, and that it may be necessary to search for the vessel continuous with that which has been wounded, should he, in the capacity of a surgeon, find that the application of a ligature to one vessel has not been attended with the desired effect.

If the surgeon has it in his option to select a portion of the artery for the seat of deligation, there can be little doubt that the lower-third of the arm should be preferred; but he may be obliged to search for the vessel higher up: in which event the same instructions will serve, even as far as the axilla, where, however, it must be remembered, that the coraco-brachialis muscle intervenes between the short head of the biceps and the vessel. The veins and nerves will occupy nearly the same relative position, only the latter will be closer to each other, and the former somewhat larger in calibre.

The drawing of the arm (fig. 126) with the dotted lines will give

![Fig. 126](image)

an idea of the position of the incisions above recommended; but it may be well to bear in mind that much longer lines than these proportions indicate may occasionally be of advantage.

When the humeral artery has been punctured in vennsection, the surgeon may wish to try the effect of pressure, before he resolves to secure the vessel with a ligature; and for this purpose each finger, and the thumb also, should be surrounded with a narrow bandage. Long narrow folds of lint should be placed over the radial and arteries, and along the humeral for two or three inches above the wound, and these should be firmly retained with a common-sized
roller, care being taken that the pressure is not so great as to obstruct the circulation completely. Mr. Tyrrell related five examples of successful practice by pressure, and the fortunate results of the recent revival of this method of treating aneurisms in the lower extremity, as alluded to in the chapter on Aneurism, give great encouragement to try it in the upper extremity, even when this disease has followed the wound in question.

Though it is quite possible that this plan will succeed in obviating the bad effects of such an injury, the probability is that it will not, and a species of aneurism will be the result. The wound in the skin seems to close as readily in these cases as if no such accident had occurred. The internal state of matters varies, however:—thus, the blood may pass directly from the artery into the vein, the two vessels being in close contact, when the latter will become much enlarged in size in the vicinity of the communication, and the branches of the former (radial and ulnar) diminished, in consequence of the usual quantity of blood not passing through them. The drawing (fig. 127) admirably illustrates the external aspect of this form of disease, to which the name of aneurismal varix is usually given, and that immediately below (128), shows the communication between the artery and vein.

Possibly one of the venae comites may have been punctured along with the artery, and the arterial blood may, by entering this smaller vessel, have caused distention of many branches, deep as well as superficial. Professor Pancoast has alluded to four examples of this form of disease, and seems to deem it of more frequent occurrence than is usually supposed. In another instance a communication may exist between the two vessels by means of a little intermediate aneurismal sac, constituting the condition termed varicose aneurism,—a term which I agree with Sir George Ballingall would be better applied to enlargements of vessels such as those last alluded to, or the dilatations of both arteries and veins, especially the latter, occasionally met with
in almost all parts of the body, and which I have alluded to in my observations on aneurism by anastomosis. Again, a large collection of blood may form in front of the elbow which may be either circumscribed by a distinct sac, or diffused extensively upwards and downwards in the course of the vessel,—of both of which I have met with well-marked examples. The transfixed vein in such cases is usually compressed by the swelling.

There is little difficulty in detecting such cases, both from their histories and condition, as ascertained by the ear and fingers, and the line of practice to be followed is in general equally clear. If there be merely a simple communication between the artery and vein, which produces but slight inconvenience, the surgeon had better not interfere. If, however, such a state of matters should be the cause of much emaciation and loss of power in the limb, as well as of annoyance otherwise, or if an aneurismal tumour should, by increasing, threaten to burst or endanger the limb by mortification, an operation will be required, and this consists in ligature of the wounded artery. The proceeding will vary according to that of the disease. Though it is admitted that ligature of the vessel at the middle of the arm in the manner already described (p. 243) will answer in some instances, it seems to be allowed by most good authorities, that the best plan is to secure the vessel at the seat of injury, by the application of a ligature above and below the wound. I have known a second operation required, within a few weeks after the humeral had been tied in the lower-third of the arm, in consequence of the continued free communication of blood from below with the opening in the artery. Mr. Collis, however, has stated (Lectures, by M'Coy) that he has never seen an instance where it was necessary to lay open the sac, having operated himself, and seen others do the same very often, using only one ligature, which was always applied close above the tumour. If the vein still carries blood, an incision about three inches in length should be made along its inner margin; and, by holding it a little aside, the artery may be exposed at the seat of injury, and a ligature put on above and below. I once saw the artery tied in this way without meddling with the communication between the two vessels. In this operation, I recommend the lower ligature to be tied first, or that both should be applied before one of them is tightened, as the pulsations will permit the vessel to be easily distinguished: for, if the upper one be first secured, this guide will be lost; and, as the vessel may have been punctured low down, the operator may have some difficulty in tracing and recognising it.

Though in an instance where the aneurismatic tumour is small the vessel may be tied as thus directed, it may be as well, however, to cut into the tumour, and evacuate the contents,—a proceeding which is absolutely requisite when the swelling is extensive. In such examples, the circulation through the artery must be checked by pressure higher up, either with the tourniquet or the fingers. If the collection of blood be great (perhaps from six to twelve ounces), the vein will in all likelihood be obliterated, or it may be impossible to
LIGATURE OF ARTERIES.

247
distinguish it on the surface; a free incision, three or four inches in length, may therefore at once be made into the tumour, parallel with the artery, and when the clots are removed, the orifice in the vessel will not be difficult to detect, particularly if the pressure on the arm above be taken off for an instant: the artery should next be carefully insulated a little above and below the wound, and the ligatures applied as directed. A probe may be passed with advantage into the orifice, to serve as a kind of guide whilst dissecting the vessel from its connexions.

Wounds in the axilla occasionally open the main artery or one of the principal branches, and the surgeon may perhaps have an opportunity of securing the vessel immediately above and below the orifice, either by extending the wound in the skin already made, as was done by Hall, or, by making a free division of the integuments and pectoral muscle, as was practised by Desault, in an example of extravasation following a sword-wound in the arm-pit.

The axillary artery is sometimes the seat of aneurism also, in which case it may be requisite that a ligature should be applied nearer the heart. If the tumour is low down, there may be sufficient room to operate below the clavicle; if it be high up, or of considerable magnitude, as is not unfrequently the case, the subclavian artery should be secured at the root of the neck, as afterwards described in the section on that part of the body; indeed, in all instances of axillary aneurism I should prefer the latter operation, as, in addition to its efficacy being equal to that of the other, I consider it less troublesome and dangerous in its performance. Some surgeons have preferred that below the clavicle, however, and it may be done in the following way:—The patient being laid on his back on a convenient table, with the shoulders and head slightly raised, and the elbow separated a little from the side, instead of cutting the skin, so as to get between the two portions of the pectoral muscle, or between it and the deltid, I recommend that a lunated incision (such as may be seen marked (a) in a drawing in the after-part of the volume exhibiting the incisions for operations on the large arteries of the neck,) should be made from within an inch of the sternal extremity of the clavicle to the point of the coracoid process, and that the clavicular portion of the pectoral muscle should be cut across in the same direction. On the dead body it is not difficult to expose the artery in either of the spaces above-named, particularly between the pectoral and deltid muscles. On the living, however, I should deem it much more troublesome. The circumstance of saving a small portion of the pectoral muscle I consider of very trifling importance compared with the advantages obtained by dividing it, and therefore I should not hesitate about selecting the operation now described. The space between the two portions of the pectoral is so small that it is far from desirable to attempt the operation there; and if the space between the pectoral and deltid is selected, the risk of wounding the cephalic vein and branches of the thoraco-acromialis artery is considerable. These vessels are in danger at the outer extremity of the incisions I have recommended; the vein, however,
may be held aside, should it be found troublesome, and from the size of the wound, the arterial branches, if any are divided, may be readily compressed or tied. When the muscular fibres are cut across,—a step of the operation which should be done cautiously on the point of the fore-finger or a director,—the loose cellular membrane and fat between the pectoralis minor and subclavius should be carefully raised and turned aside; the vein will then be brought into view, when, by having it held a little downwards with a blunt hook, or spatula, the artery will be discovered, and may be laid bare, but to such an extent only as to allow the needle to be passed around it, which should be done from below upwards, care being taken, by keeping the point in contact with the vessel, to exclude any branch of the axillary plexus of nerves, all of which lie on its upper and posterior side. If the patient is unsteady, or the surgeon is unwilling to use the blade of a common scalpel in the bottom of the wound, he may advantageously separate the fat and cellular tissue near the vessels with the handle of the instrument, or tear with a blunt steel or silver spatula, which cannot endanger the division of any more important part.

Notwithstanding the success of this operation in the hands of Keate and Chamberlayne, and that it has occasionally been practised and recommended by most competent authorities, it appears evident, either that the cases admitting or requiring the operation are few in number, or that a very general preference has been given to that of Mr. Ramsden above the clavicle, which in the present day seems the only method pursued in axillary aneurism, unless it be to trace the subclavian still nearer the heart. In examples of wounds of the axillary artery, it must, indeed, be rare to meet with such an instance as that which occurred to Mr. Hall (Bell on Wounds, p. 60, 3rd ed.), which, however, was only in the upper part of the humeral. It will more usually be observed that the injury to the vein, nerves, and other textures, leaves so small a chance of the arm surviving, that the surgeon may reasonably take into consideration the propriety of amputating at the shoulder-joint. A most interesting case of diffused aneurism in the axilla, the result of an injury (dislocation, I believe, of the shoulder), occurred many years ago in the practice of the late Dr. Nicol, of Inverness: Mr. Syme placed a ligature on the subclavian above the clavicle, but the hemorrhage still seeming to go on, amputation at the shoulder-joint was performed (Syme's Principles of Surgery, 115, 3rd ed.), and the result was successful. No time elapsed in this instance, after ligature of the artery, to permit the occurrence of gangrene, as happened in the case related by Mr. White, and also in that which occurred to Desaill, in both of which, had amputation been performed, instead of deligation of the main artery, the patients would in all probability have been saved.
CHAPTER V.

VENESECTION.

In the present practice of Physic and of Surgery in this country, a chapter on this subject might be omitted without special remark, but forty years ago no minor operation was of more importance unless I except that of "cupping." I have a fancy, however, that in subsequent years venesection may again come into use, and having practised it frequently in my youth, I deem it best to retain the following chapter.

The operation of venesection may be done as follows:—The fore part of the elbow should first be examined with the fingers, to ascertain the position of the humeral artery, and that there is no irregularity in it or its branches: a common bandage or a riband, about a yard in length, should then be carried round the arm three or four inches above the elbow, and drawn sufficiently tight to prevent the circulation in the veins; that in the artery being allowed to go on with full vigour, as may be ascertained by feeling the pulse at the wrist. Then, in order to throw the most of the venous blood into the superficial vessels, the patient should be desired to put the muscles of the fore-arm into action, which, for this purpose, can be best done by grasping some object with the hand. One of the veins at the bend of the elbow must next be selected for the operation: either the median basilic or the median cephalic. If the latter be chosen, there is no danger of doing any harm with the lancet, unless it be to a branch of the musculo-cutaneous nerve, which some suppose may cause trouble; if the former (median basilic), then all care must be taken to avoid the humeral artery, which will probably lie immediately beneath, only separated from the vein by that part of the aponeurosis of the fore-arm, which passes from the inner margin of the tendon of the biceps. In operating on this vein a branch of the internal cutaneous nerve may be cut, but there is little occasion to dread the supposed effects of such an injury. Notwithstanding the position of this vessel over the artery, it is commonly selected, being in general the larger of the two, and therefore the most likely to yield with ease the desired quantity of blood. After the bandage has been applied for a few minutes, the thumb of the surgeon's left hand should be put upon the vein a little below the part incised to be opened, and the lancet, represented at p. 55, held as in figure 129, between the thumb and forefinger of his right
hand, should be pushed through the skin into the vein, in such a
direction as to cut it obliquely; the point of the instrument should
then be raised, so as to describe the segment of a circle, and thus the
wound in the vessel will be nearly as large as that in the skin. Were
the lancet thrust in and drawn out again, in consequence of the shape
of this instrument, a sufficient opening could scarcely be made, without
transfixing the vein. Instead of holding the lancet almost at a right angle
with the vein, as represented in the drawing, it may be placed in
a line more parallel with the thumb, and thus it will puncture at a less
acute angle than the sketch indicates. Besides keeping the skin and
the vein steady, the thumb, placed as above directed, commands the
flow of blood, until a dish convenient for its reception is held opposite
the wound: the thumb being raised, and the quantity of blood re-
quired allowed to escape, the bandage should be loosened, when
the stream will immediately cease to flow. A few folds of lint or
linen rag, about two inches square, should then be put over the wound,

care being taken that its edges are in close contact, and a bandage
(probably that already used) should be put round the elbow in the
form of figure 8, the arm being kept slightly bent.

This is one of the operations where it will occasionally be more
convenient to use the lancet with the left hand than with the right.
In opening a vein of the left arm, for example, it will be best to use
the left hand, as the surgeon can stand behind the arm, and avoid
the first jet of blood. In all instances of this operation, every care
should be taken to perform it in as cleanly a manner as the circum-
stances will permit, so as not to bespatter any of the surrounding
objects, particularly the patient's body or bed-clothes, and the more
effectually to guard against this, the precaution of placing a towel to
protect the parts beneath should not be omitted.

It is seldom indeed that any evils result from the above operation,
such as they are may be treated according to the principles in-
culcated in the introductory sections of this work on wounds, he-
morrhage, inflammation, and its consequences, &c., or in accordance
with the practice recommended in the preceding chapter, for injury
of the humeral artery occurring during the use of the lancet in this
situation.

CHAPTER VI.

EXCISION OF THE MAMMA.

The course of the external incisions for this operation will vary in
different cases, according to the size and shape of the disease. In some
examples I have made vertical incisions like either of those here
exhibited (fig. 130); but in the generality of cases they should be
made nearly in the course of the fibres of the great pectoral muscle,
as exhibited in the next drawing. The operation may be performed in this way:—The patient should be seated on a chair, or, what will be better, particularly where anaesthesia is used, laid on a table, and the elbow on the affected side held out from the body so as to throw the pectoral muscles on the stretch. If the tumour be small a single line of incision may suffice, but as the nipple and the skin may be affected lunated incisions should be made, with scalpel, or bistoury, along the surface of the tumour to include the disease; the skin should next be separated from it; the wounds should be carried as deep as the pectoral muscle if necessary; and the mass should be dissected out, by cutting in such lines as may seem most convenient.

In this proceeding, as in others where the disease is supposed to be malignant, the surgeon, as already stated in my remarks on tumours, can scarcely err in taking away too much. Fortunately, the skin is usually so lax in this situation that there need be little fear of not being able to bring the edges of the wound into apposition, and the first incisions should therefore be made at such distance from each other, as not only to include the affected part, but also a portion of the healthy textures, and the knife must subsequently be carried to such a depth as to secure the complete removal of the disease. The pectoral muscle must be laid bare in many instances, and even portions of its substance removed should the mass be connected with it. Four or six arteries may bleed actively, and should be compressed by the assistant’s finger as soon as cut. When the tumour is removed, ligatures should be applied wherever required. I have known only one necessary; and again I have frequently used eight, or even a dozen. The wound should then be dressed and treated according to the ordinary principles of surgery. If the edges can be brought accurately into contact, adhesion may be obtained at once; if not the wound must of course heal in a slower manner by suppuration and granulation.

The following drawing (fig. 131) will serve as an outline of the position of the patient, that of the surgeon, who may be imagined to be on her right side, and the style of making the incisions. The tumour may here be supposed to be small, but frequently it will be much more extensive than is represented.

It is often requisite in the removal of the mamma to take away at the same time diseased glands in or near the axilla. For this purpose, the extremity of the wound nearest the armpit should be extended by an incision into this space, when, by separating its edges, the glands may be uncovered, and, if they are small and loosely connected, the knife may be carried round them on all sides. A cutting instrument cannot be used too cautiously in this space, however, and it will be safer to use the fingers a good deal, so as in a manner to tear out the glands, only making small incisions from time to time, when the cellular membrane does not easily give way. When the textures about to be cut cannot be readily seen, and when there is any suspicion of a vessel
of magnitude being in danger, the glands should be separated from
the surrounding connexions as well as can be accomplished by
moderate force with the fingers or handle of the knife; and after a
loop of strong thread has been east around the deep tissues, the knife
or scissors may then be applied between it and the part to be removed.

Fig. 131.

In some instances the diseased glands are so near the mamma, and so
loosely connected, that they may be dissected out at the same time,
and with the same incisions; but it is often more convenient to take
away the large mass first.

These proceedings in the axilla are almost invariably attended with
more trouble than the other steps of the operation: to facilitate
them, and in some degree to avert the danger of cutting in this
situation, I strongly recommend that a free opening should be made
in the skin, and that even a portion of the lower margin of the large
pectoral muscle should be divided, instead of attempting such
manoeuvres through a small separate aperture on the surface, as has
been advised by some. In some instances I have experienced ad-
\textit{vantage by not separating the mamma until the glands in the axilla
were fairly isolated, having held it and intervening substance as a
kind of lever to facilitate the loosening of the parts about to be removed
from the axilla.}

It will be found difficult to hold and elevate the diseased glands,
either with the fingers, hooks, blunt or sharp, or with the common
dissecting forceps; and, in preference to the plan of passing a needle
and thread through them, using the vulsellum or any other method
with which I am acquainted, I often make use of the hook-beaked for-
ceps represented in p. 31, but of a larger size, and occasionally I find
the lion forceps afterwards depicted of great service in such pro-
ceedings.

In giving these directions, and speaking so familiarly, as it were,
of removing enlarged glands from the axilla, as part of the operation
for excision of the mamma when affected with malignant disease, I beg
it to be clearly understood, that I am by no means an advocate for the use of the knife when, in such cases, the axilla has become the seat of malignant action. There are some instances, however, when the glands are but slightly enlarged (perhaps merely from irritation) and loosely connected, when it may reasonably be deemed advisable to operate, and it is in these (and where the glands ought not to be left on the supposition that irritation is the sole cause of their enlargement), that the above directions are applicable.

CHAPTER VII.

INCISIONS. EXCISIONS.

Besides incisions for operations on the arteries, there are many others required in practice. Thus, a wound, about an inch in length, along the margin of the palmar surface of a finger, may lay bare a digital twig. An incision about one inch and a half in length between the flexor carpi radialis and the flexor sublimis, a little above the annular ligament, will expose the median nerve in this situation. Such operations are occasionally deemed advisable in cases of tic douloureux; and many years ago I assisted my friend Dr. James Simson, of Edinburgh, to perform the one last referred to, in an instance in which the nerve had been cut across by accident, about an inch above the wrist, where it was proposed to restore its continuity, and thus, perhaps, the lost sensibility of the side of the hand supplied by its branches. The ends of the nerve were found in the cicatrix; but unfortunately, a small tumour, such as is occasionally seen on nerves after amputation, which had formed on the extremity of the upper portion, necessitated the removal of about an inch in its length; the two extremities were brought into as close contact as possible,—they could not be brought to meet, but the favourable result which might have been reasonably expected, if there had been no loss of substance, did not take place.

Years ago I had a very interesting operation of this kind on the arm of an old lady, a patient of the late Mr. Squibb, of Orchard-street. There was a tumour about the size of a hazel nut in the palm of the hand, where the branches of this nerve, leading to the fingers, are situated, so exquisitely painful as to lead to the suspicion that it might be a growth in the substance of one of them, or that it might so press upon them all as to cause the pain. The growth had been of many years' standing, and the pain had continued to increase gradually, notwithstanding all that could be done by the most skilful who had been consulted. I suggested division of the median nerve, and the operation was done accordingly, in the situation indicated in the commencement of this chapter. For a few days it was thought that the pain had left, but then it recurred, although it was not so severe as
formerly. The benefit of the proceeding fell far short of my expectations, and I have little doubt that the tumour was different from an ordinary neurinm. I have since had a case of a similar kind, but with no better result.

In an instance of painful ulcer on the arm, a little above the inner condyle, I have seen a portion of the ulnar nerve, supposed to be involved in the sore, removed with excellent effect. The painful open surface which had been present for many months, and resisted all attempts to cure, speedily put on a more healthy aspect, and the operation, although it deprived the little finger and the ulnar side of the ring one of sensibility, was attended with all the benefit that could have been desired.

Incisions are sometimes made in cases of erysipelas, and a knowledge of anatomy will indicate the safest places for applying the knife on such occasions; they are required too, in whitlow in the fingers, in suppurations, for the removal of tumours, of diseased or dead portions of bones, and occasionally also for false joints. In all these operations, the general rule of cutting parallel with important parts, should be carefully kept in view. In certain instances it will be absolutely necessary to sacrifice some tendon, large nerve, or vessel: about the wrist it may sometimes be deemed advisable to dissect out wens, ganglions, or solid tumours, and it will scarcely be possible to avoid the division of some such textures; yet, by great care, most of the important parts may be avoided even here. I have often succeeded in removing ganglions from the back of the wrist without dividing any tendons, although the tumours lay close upon the carpal bones; and in one instance I removed a large, firm, fatty tumour from the front immediately above the wrist, although it dipped among the tendons, and actually touched the pronator quadratus. I should wish it understood, however, that I do not recommend operations in such cases unless there is some good reason; for at all times there is danger of severe inflammation coming on, which may leave the wrist in a stiffened condition ever after. I should say the same, too, for chronic collections of fluids in the sheaths, either of the extensors or flexors of the fingers,—for although instances are not wanting to show that injurious inflammation does not invariably follow, the surgeon will do well to calculate the chances of such an occurrence, and therefore, whether he does right in submitting his patient to such a probability.

In swellings depending on effusions, I have occasionally, as already stated in my remarks on the treatment of tumours, succeeded in curing these affections without incisions; but they are sometimes necessary. Occasionally loose fibro-cartilaginous bodies are observed in these sheaths, which can be got rid of only by the knife. Some time ago I treated a case of the kind in the sheath of the flexors of the middle finger: there was a considerable swelling extending the length of the two proximal phalanges, which prevented the patient from closing her hand: an incision about an inch in length permitted the escape of several hundred of these little objects, when, by accurately closing the
wound and keeping the finger steady on a straight splint for a few days, a cure was the result. The swelling had been twice punctured before with a lancet, which only allowed the fluid to escape, whilst the bodies, being retained, acted as the cause of future effusions. Surgeons have probably erred in being too cautious with incisions into such chronic collections. It seems harsh and cruel to make a large incision in the quiescent state of such swellings, yet I believe that such a practice may be safest and best. In tumours of the sort in front of the carpus, in the sheath of the flexor tendons, Mr. Syme has recommended the division of the annular ligament. In some large collections here I have occasionally been content with punctures, and sometimes I have made incisions. In these cases the practice has mostly been palliative. But when a free incision has been made the cure has been complete, although sometimes with deficient play of the tendons afterwards, owing to adhesion. In one case, when the swelling was conspicuous in the palm of the hand and above the wrist, I made an incision about three-quarters of an inch in length above the wrist to permit the free escape of the glairy fluid within; a violent inflammation followed; the cavity was filled with bloody sero-purulent matter and air; the swelling in the lower part of the arm and hand was considerable, and there were great tension and pain. A free incision parallel with the tendons was made up the fore-arm with great relief almost immediately, and everything went on satisfactorily afterwards. Here the free incision, I believe, saved the hand, and probably the life, of the patient, and although the annular ligament was not divided, I can conceive the advantage of such a practice in certain cases. I am disposed to think, from what I have seen, that the danger which is usually considered attendant upon punctures or small incisions in these cases, results probably from the very means which the surgeon fancies to be the safest. Certainly, if there be alarming inflammation after punctures there should be no hesitation or delay in making a free opening into the inflamed parts.

Little ganglionic tumours are occasionally noticed on the knuckles, developed in small bursæ which are said to occupy these points; I have met with cases of the kind, and the swelling was most distinct over the back of each joint between the first and second phalanges of the fingers. Over the olecranon well-marked examples occasionally occur in gouty subjects, varying in size from a walnut to a lemon. Although it may be doubted whether a bursa occupies this situation in all individuals, it cannot be denied that, in many who are in the habit of leaning much on this part, such a condition obtains, and the swelling is liable to attacks of inflammation, similar in most respects to those which are seen in the bursa over the patella. The condition, from being seen so often in those who work on the side in low-roofed mines, has received the appellation of "Miners' Elbow." The treatment may be conducted according to rules inculcated in other parts of this volume, more especially with regard to the affection familiarly known as "the Housemaid's Knee," to be afterwards noticed in the section on the inferior extremity.
The bursa under the acromion is sometimes the seat of serum or pus, but unless to caution a young practitioner against mistaking these for disease of the shoulder-joint, I know of no observations peculiarly applicable to such cases, further than those detailed in other pages.

In my remarks on fractures of the upper extremity, I have exhibited a drawing of a false joint in the ulna, succeeding to such an injury. Here it might be thought advisable in the course of treatment to expose the callous surfaces by means of incisions, and then to proceed in the manner recommended in the chapter on False Joints. In such an operation, if the radius were entire, it might be difficult to evert the fragments of the ulna. Any portion of the last-named bone might be easily reached without touching important parts, by dividing the skin along the ulnar side of the limb. The radius, however, could not so easily be exposed,—indeed, unless in its lower-third, it could not be got at without dividing muscles; and were the false joint so placed, I should in most instances question the propriety of interfering in this way at all, as I cannot imagine that non-union would cause such serious inconvenience as to necessitate such a proceeding. That the surgeon may occasionally interfere, however, in this way, must be admitted, for an interesting case of the kind is related in the London and Edinburgh Monthly Journal of Medical Science for October, 1841, where excision was performed on the fragments of the radius, and those of the ulna were treated with the seton,—success following in about twenty months from the receipt of the injury, which was a compound fracture occasioned by the bursting of a gun.

In false joints after fracture of the olecranon (p. 232), I think it would in general be best to let matters alone. I have seen a person make excellent use of the arm in such a condition.

In the shaft of the humerus it is evident that, in false joint, the extremity would be of little service, and if milder measures did not answer, supposing the patient were willing to take his share of the risk, I should not hesitate about denuding the ends of the fragments, and such an operation might be readily and safely accomplished on any surface of the limb, excepting that on which the artery is placed. After using the knife, and treating the ends of the bone as might be deemed advisable, the wound should be brought together by stitches and straps, and, the fragments being placed in proper position, the future treatment might be such as in a case of compound fracture. Even here, however, although it was the instance where Mr. White introduced this mode of practice, I have known the proceeding fail in its object. In fractures occurring in early life where union has not taken place, or where there has been neglect, the ends of the fragments occasionally, or perhaps always, remain imperfectly developed, and, in these instances, I believe that surgery can do little or nothing.

In various parts of the arm incisions may be required for caries necrosis, or sinuses, and my experience induces me to give caution regarding divisions in the line of the musculo-spinal nerve or its branches. I have seen more instances of paralysis of fingers and forearm from them than from any other in the upper extremity.
Various remarkable congenital malformations are met with in the hand. Sometimes there is a deficiency of the natural parts, and in other instances there is a redundancy. In the former cases the surgeon can do nothing, but where there is an unseemly plurality the surgeon may display his ingenuity by removing the superfluous appendages. The instances which have chiefly come under my notice have been examples of additional thumbs or little fingers; sometimes on one hand only, but more frequently on both at the same time. The additional fingers, although in most respects perfect in their outward appearance, have been attached at the distal end of the metacarpal bone by skin only. I have never seen any difficulty in discriminating between the proper finger and the supernumerary; but with the thumb it is sometimes difficult to say which is the true member. Here is a drawing of an example (fig. 132) of the kind, taken from the right hand of a very able sculptor. In some of these instances there is such a disposition of tendinous fibres that in the course of time the person gains a very tolerable use over the appendages; and, as the principal organ is deficient in development, there is a kind of compensating power given by the movements of both. I have seen an instance where the person could move the two portions as if they were imperfectly developed fingers, and the individual was quite contented with his condition. In general these abnormal developments are greatly in the way and most unpleasant to look at. If a person is allowed to carry them with him to mature age, he will possibly not care to part with them, but in all instances, it is my opinion, that the superfluous parts should be removed in early infancy. I have performed many of these operations, and have never seen any evil whatever result. On the contrary, a most disagreeable appearance has been removed, and the hand has been allowed to increase in its natural way. In noting the history of such cases, I have often been amused how mothers, impressed with the common errors as to the causes of such malformations, have accounted for the way in which they must have been caused. One told me, when I had to remove a superfluous little finger on each hand, that she had got a fright during pregnancy by seeing a boy run over by a street cab, and getting a finger cut off in the injury! Why nature should thereafter have provided her embryo child with an extra finger on each hand she could not explain.

Of a similar character are those examples of defective development when the fingers, hand, or fore-arm are more or less partially deficient, or when the fingers are attached to a stump on the shoulder or side of the chest. The surgeon cannot pretend to do anything in such cases, but as a physiologist he may, I think, laugh at the idea which I once...
heard a mother announce, that the cause why her son was born without a hand and half of the fore-arm, was that she sat at dinner once during pregnancy opposite a naval officer who had undergone amputation in the thigh!

Among the congenital malformations of the hand which are occasionally met with, such as that here represented (fig. 133) may call forth the surgeon's ingenuity. The boy from whose hand this likeness was taken had web toes as well as fingers, and in the latter the union between the ring and middle fingers was most conspicuous. The bones and tendons of each seemed perfect, but the two were wrapt as it were in one envelope of skin. Under the impression that this tissue was sufficient to give a good covering to both fingers, I ran a bistoury between them up to the proper place of divarication, and then by means of stitches brought the skin on the back to join with that from the palmar aspect on the side of each finger: union took place throughout the greater part of each wound; by further careful dressing, so as to approximate the skin from the anterior and posterior aspects of the hand, at the root of the fingers, the parts were left in the condition figured in this drawing (fig. 134), and the boy speedily began to move each member separately. Unless great pains were taken in dressing such a wound, the parts might resume their original condition, and this is particularly apt to occur in instances of such deformities produced by burns. It is not unusual in the contraction of granulations resulting from the last-named injuries that one or more fingers are
joined together, or possibly turned forwards or backwards on the hand; they may, however, be dissected from their unnatural position, and at the same time separated from each other, so as to admit of some improvement in the state of the organ. No set rules can be given for such proceedings; but where the surgeon has the chance of leverage, it is astonishing how much can be done, in some of these cases, with well adapted apparatus.

Such a condition as that represented in the next drawing (fig. 135) has occasionally been the subject of operation. The hand here exhibited shows the little and ring fingers in a state of permanent contraction. At first this affection shows itself by slight inability to extend one of the fingers (generally the little one), which is ultimately, in the progress of years, crooked up into the palm: by this time the ring finger will also have assumed a nearly similar state, and possibly, too, the middle finger will be somewhat rigid. At first sight, in such a case as this (well displayed in the drawing), the flexor tendons seem to be the cause of this distortion; but the dissections of Dr. Goyrand and others have shown that the cellular tissue between the skin and palmar aponeurosis usually gives rise to it,—a view which I imagine to be very correct in a majority of these cases, as seems clearly indicated when the rigidity is first observable on the palmar aspect of a finger. Dupuytren asserted that the palmar fascia itself was the chief cause. In all instances where the contraction has been extreme, it has appeared to me that skin, cellular tissue, fascia, and even tendons have been more or less in such a state of permanent rigidity as to prevent the extension of the fingers; indeed, I have observed in the dissecting-room, that in cases of old standing, when all the textures were removed with the exception of the ligaments, the fingers could not even then be stretched out without force, and that they immediately afterwards, unless when the ligaments were torn, resumed their crooked position. In some cases I believe that one or other of the textures above-named may be more in fault than the rest, and in others that even the lumbricales and interossei are in part the cause.

It has been asserted, that those who are so employed as to cause much pressure on the palm (such as carpenters, gardeners, gunners, &c.) are more subject to this condition than others; it may be so, but the figure above exhibited was from an individual who had been less occupied in this way than most people, and I have again and again seen the fingers thus distorted in parties who never had occasion to put their hands to any kind of rough work.

Such cases may be treated with subcutaneous division of the rigid
textures, and when extension alone will not suffice, it is a method which, in many instances, I consider preferable to any other. A narrow knife should be pushed under the skin in front of the contraction, and then carried through the most prominent band, whether this be merely the aponeurosis, condensed cellular tissue, or tendons, and thereafter the fingers should be gradually extended on a splint by means of bandages. The latter apparatus must be constructed by the ingenuity of the surgeon to fit the peculiarities of the case, and I believe that a clever adaptation of such means may go far to obviate and even remove various deformities in the hands and fingers resulting from the causes above referred to, as was proved many years ago by M. Dutertre, who, in 1814, published some most interesting cases of successful practice, by means of incisions and apparatus, in removing adhesions, contractions, and distortions, resulting from burns. In all instances when the parts are divided as here recommended, the extend-

*Fig. 136.*

ing apparatus should be worn for a considerable time afterwards, as there is great disposition to contraction again: indeed, so much is this the case, that if the offending part were very superficial, I should be inclined to dissect a portion of it out at once.

In many cases, I believe, this last-named practice should be resorted to at first. An incision should be made lengthwise through the skin over the whole of the contraction, and if the integument be tolerably soft and thick, it should be turned off on each side, so as to expose the fibrous tissue, which should then be carefully cut away. To effect this satisfactorily, it is sometimes advisable to make one or more cross incisions in the skin, for this tissue, having been long contracted, does not stretch so readily as in the healthy state. In any, or all of these operations, the utmost care should be taken to avoid the nerves and blood-vessels at each side of the finger, and if the stretching can be satisfactorily effected without opening a sheath or touching a tendon,
INCISIONS. EXCISIONS.

261

so much the better, as then some movement might be expected afterwards; but if the tendons require division, the finger must remain stiff; and, in anticipation of such an event, it will be well to consider what good can be expected from the proposed operation.

Contraction at the elbow, from burn or seald in front, is by no means uncommon. The plan of treatment above recommended will be found of great service in many such cases. Figure 136 represents one of the worst of the kind I have ever seen. By neglect and improper treatment of a charlatan, a large sore, resulting from a seald, was allowed to contract and convert the arm into this condition. Besides its unseemly appearance, the arm could not be stretched more than is represented in the cut. By a longitudinal incision on the most prominent part of the cicatrix, the fibrous tissue underneath was exposed, and cut away, when the arm could be stretched considerably; but some transverse incisions then seemed requisite, and several were made on each side through the skin and cicatrix. Further extension was thus permitted, but not to the extent that could be desired. By gradual means, however, the arm was in the course of ten days fully stretched, and after the lapse of four months the limb presented the appearance in fig. 137. The granulations resulting from the wounds had not entirely healed when this sketch was taken, but everything appeared in a favourable way, and the patient could move her arm in flexion and extension with great facility.

The thumb seems occasionally to be affected in such a manner as to prevent a person using a pen, and from the condition having been seen in those chiefly occupied in wielding this mighty weapon, the unhappy state has received the elegant and appropriate denomination of "Scrivener's Spasm." Stromeyer has succeeded in the eure by dividing the tendon of the long flexor. I have met with many cases of the kind. In these instances the pen can be held in the usual way, but as soon as its point is put to paper, and an effort made to move it, a sudden

Fig. 137.
spasm seems to seize the flexors, when the fingers and hand are bent inwards against the utmost effort of the sufferer, so that he cannot form a single letter distinctly. The arm usually presents a healthy appearance. I have seen a person much occupied in literary pursuits complain of a condition the reverse of spasm, being unable to hold the pen steadily so as to guide it along the paper—a state which appeared to me the result of over-fatigue. Those who are fond of quaint names might call this the "Serivener's Palsy," in contradistinction to the other. Neither of these conditions demands any operative interference, and I believe that the best mode of treatment is to attend to the general health. I have known some cases recover, but many have resisted all rational modes of treatment.

I have successfully divided the tendon of the flexor sublimis con-
nected with the ring finger and also that of the profundus, above the wrist, for permanent contraction of the part, and I have seen the tendon of the palmaris longus cut across by subeutaneous incisions with excellent effect, for similar distortion in the wrist.

Incisions may be required in various parts of the extremity for the removal of diseased or dead portions of bone, and, with few exceptions (as the elbow and shoulder-joints), no set rules need be stated for such operations, further than those which must be apparent to any one at all acquainted with anatomy and pathology. I refer to my remarks on amputations of the metacarpal bones, as explanatory of my own views on some of these points. A good anatomist and judicious sur-
geon may do much in many of these cases to obviate the necessity for anputation; but I doubt if there is much utility in practising on the dead body resection of the lower ends of the bones of the fore-arm, of portions of their shafts, or the whole of a single bone. It is customary in what may be termed "dissecting-room surgery," to exhibit such operations; and numerous drawings have been published on the subject, which, however, in my opinion, give a very inadequate idea of anything like good surgery, applicable to the living body. These usually exhibit a portion of bone with a sort of mock disease upon it, and a gash in the soft parts sufficient to appal even the most stout-
hearted. The muscles and neighbouring tissues are displayed as if for demonstration, and the whole appearances bear scarcely a resem-
bance to what will be met with on the living subject. For example, in excision, unless the operation be a primary one, as when the end of a bone has been exposed and injured, the diseased or dead portion is generally surrounded by thickened cellular substance so infiltrated with lymph as to obscure the healthy natural appearance; it is only when the incisions are very extensive indeed that muscural fibres are seen at all, and even then they are exposed to a very partial extent. Portions of the shaft of one or other of the two bones have been removed with success, sometimes at their articular extremities, in other instances towards the middle of each. I have often, with the aid of the cutting forceps and gouge (p. 9), removed portions of the bones of the hand, wrist, and fore-arm, and seen others do the same; but in the latter region I have rarely seen any instances where resee-
tion of the entire thickness of a bone has been required. Examples of the kind, however, have been published by American and continental surgeons; and with a knowledge of anatomy and of the principles of surgery, I thoroughly encourage such laudable attempts to save a patient's hand. Many years ago my friend Dr. McEwen, of the Chester Infirmary, consulted me regarding a case of disease of the ulna, which I advised him to remove by excision. More than six inches of the lower end of the bone was taken away through a longitudinal incision on the inner margin of the fore-arm, and that gentleman informed me long after that the arm was perfectly well, and the use of the hand complete; the case was published in the Provincial Medical and Surgical Journal, 4th September, 1844.

Since these observations were written for an early edition of this work, my experience in excisions in the hand and fore-arm has been largely increased, and I am convinced that there are few instances of caries or necrosis in this extremity in which amputation need be performed. When the fingers or metacarpal bones are involved, it will be well to take into consideration the probable after-utility of the part which it may be desired to save. It is often possible, by the removal of a portion of bone, to save a finger tolerably whole, yet it may be so stiff and useless, and, withal, so much in the way after, that the patient will often have reason to regret that it was not removed at the time an operation was performed. But if, by any ingenuity, the hand itself can be preserved, however mutilated or stiff it may be, it will in all probability excel in utility any substitute that could be provided. Acting on these views, I have often, in the latter years of my practice, saved portions of the extremity, which in earlier times I should have removed. Occasionally I have been disappointed, and been obliged ultimately to amputate, but even at the risk of a second operation being required, I believe it is the safe side to err upon. Within the last seventeen years I have repeatedly performed excisions of the whole of the carpus with the contiguous articulations, but I am yet sceptical as to the result of such an operation. In strumous disease of the bones and articulations in this region, the mischief is often so extensive that, with tendons and bursæ around, a healing action comes but slowly. In the instances in which I have operated, the reparative action has afterwards been very slow and often not satisfactory. I am not aware that the proceeding had been previously attempted, but within this period Mr. Stanley of St. Bartholomew's, removed a diseased carpus with satisfactory results, and recently much credit is due to Professor Lister of Edinburgh, for placing this operation among the legitimate resections, as has been admirably evinced by his papers on the subject in the Lancet for 1865.

Resection of the wrist may be done in various ways. The incisions must be made chiefly behind or at the sides, the parts in front being too important to be interfered with. One or more of the sinuses may be laid open (care being taken of tendons), so as to permit the application of instruments and the removal of bones or fragments; or a transverse incision may be made on the back of the wrist or hand,
through which the extensor tendons can be cut across, the diseased parts reached and removed; or by an incision on the radial and another on the ulnar side of the wrist, parts may be attacked. Of these plans that of dividing the tendons I think least of, although the proceeding was successful in Mr. Stanley's case; and after trial of various methods I have come to the conviction that the operation may be most efficiently performed, and with the best prospects of a satisfactory result, by making a single incision along the ulnar side of the joint. Supposing a case like this (fig. 138), an incision in the line indicated, about six inches long,

Figure 138.

may be made between the flexors and extensors, without dividing a tendon of either, sufficient to permit the removal of the whole carpal bones, and even the articular surfaces of the bones of the fore-arm or of the metacarpal range. A narrow saw may be required if bones need division, but the forceps represented at page 9 will generally be found effectual. Neither ulnar nor radial artery need be cut, and should the interosseal or any other branch seem to require ligature there can be no difficulty in its application. Of all the principal resections associated with modern conservative surgery this is the one in which I have at the present time the least reliance; yet I think it worthy of further trial, for in whatever state the hand might be left, I believe it would prove more valuable in all respects than any artificial substitute. I have often been asked what utility there could be in saving the hand with a stiff wrist, as might be expected after such an operation. My answer has always been, that a hand with a stiff wrist is decidedly better than no hand at all. On this point we have ample experience in the instances of ankylosis in this locality, which often come under notice, and also in those cases where artificial substitutes are used in lieu of the hand which has been amputated.

I have never had occasion to remove the whole of either bones of the forearm, but I have frequently taken away large portions of the radius and ulna with the most satisfactory results. Dr. Butt, of Virginia, and Dr. Jones, of Jersey, have taken away these bones from end to end, and with success sufficient to encourage the practice. Here is a sketch (fig. 139) from a cast in the museum at King's College, taken five years after I had removed the greater portion of the radius. In this instance there was necrosis of the middle of the radius throughout its thickness,
with a swollen, softened, spongy, and probably carious, state of the bone above and below, but within about an inch of each extremity the bone was in a healthy condition. By a free incision on the radial margin of the limb it was easy to lay bare the surfaces for the application of the saw and cutting forceps, and the whole proceeding was as simple

Fig. 139.

as an operation of the kind could be. Many months elapsed before a firm cicatrix formed. This ultimately took place, and the motions at the wrist and elbow were nearly perfect when the patient went from under my notice; at first the hand was on a line with the fore-arm, but partly from neglect, and partly, doubtless, from contraction, it gradually got bent towards the radial side of the fore-arm, and the end of the ulna became prominent, as in a badly set fracture of the radius.

This sketch (fig. 140) represents the condition of the arm after

Fig. 140.

resection of the whole of the ulna, with the exception of a small portion of its inferior extremity. In this instance the articular surfaces of all the bones of the elbow-joint were removed, and the results were as satisfactory as could possibly have been anticipated. There was a stiff elbow, but very free use of the wrist and hand, when the cast, from which the above sketch was taken, was made some years after the wounds from the operation had completely healed, at which time the lad could follow his occupation of a paper-stainer. Both of these cases were published at greater length in the first numbers of The Medical Times and Gazette, January, 1852, and were among those I selected as illustrative of that style which has since become so familiarly known under the appellation of "conservative surgery."
Since these remarks were written for a previous edition, I have removed a tumour of the lower end of the ulna involving about two inches of its lower extremity. The tumour, about the size of a small lemon, had much the appearance of melanosis. The wound healed kindly, and the patient has for many years had perfect use of his hand.

Within these twelve months I have seen, in consultation with Mr. Hancock, a most remarkable example of disease and conservative treatment in this locality. A young lady had been distressed for years with a gradually increasing tumour in the fore-arm. When I saw her first the condition was such as is here represented (fig. 141). The huge tumour was evidently confined to the radius, and there was no appearance of malignancy. With great and good judgment, in my opinion, Mr. Hancock resolved to attempt excision of the tumour with a view of saving the hand. An operation was done accordingly, and this figure (142) represents the limb some months after the wound was closed. A portion of the lower end of the ulna was removed, as it was thought, during the operation, that it might prove troublesome afterwards, owing to contraction and retraction of the soft parts. Mr. Hancock has informed me lately that he had received a most gratifying letter from the young lady’s own hand, thus preserved, thanking him for his happy exertions in her behalf.

The articular ends of the bones composing the elbow-joint are frequently the seat of injury as well as of incurable disease. The general characteristics of disease of this complicated articulation may be gathered from the remarks on affections of the joints in Chapter xxiv., but there is one feature which I think deserves especial notice, as I believe that when it is present all hopes of cure for years to come may be set aside. This feature is an elasticity about the joint, which can be appreciated by pressing the ulna against the end of the humerus, as also by swinging the fore-arm laterally. If there is much mobility and elasticity under such movements I consider the joint most
seriously involved, and that in all probability the best treatment will be resection.

The operation of excision of the elbow-joint recommended towards the end of last century by Park and the Morcaus, has now been so frequently performed with happy results, as to induce most surgeons of the present day to give a patient the chance of saving an arm, which, forty years ago, would have been doomed to amputation.

In the early part of the present century, notwithstanding the excellent treatise on Excision of Carious Joints, published in 1806, by Dr. Jeffray, of Glasgow, such operations seem to have attracted but little attention from the practical surgeons of that period. To M. Roux and Sir Philip Crampton we are largely indebted for the revival of excision of the elbow; but to no one, so far as I am aware, is there so much merit due on this score as to Mr. Syme, who has, I believe, within the last forty years had more personal experience in this proceeding than any other practitioner.

The operation is most successful in young patients, but even in the adult there is ample proof that it may be done advantageously; and although bad consequences have followed in some examples, amputation would not, in all probability, have been attended with better results. When a patient dies after amputation of a limb, no properly educated surgeon would ever dream of denouncing this operation, or stating that it should never be done again; and excision of the ends of some of the bones, particularly of those of the elbow, seems to me of such undoubted utility, that the circumstance of certain examples having terminated unfavourably ought in no degree to be admitted as a just argument against the general performance of such operations. Any surgeon may amputate an arm, but when once done, it can never be replaced; and no artificial apparatus can be compared, either in appearance or usefulness, with the parts, whatever their condition, after successful excision in the elbow-joint.

The main object in such a proceeding is to remove all the diseased portions of bone, and this ought to be accomplished with as little injury to the surrounding structures as circumstances will permit. By laying open certain sinuses, which exist in some instances, and at the same time are conveniently situated, sufficient room may be obtained, but in general it will be better to make a single line as was originally recommended by Park, a crucial incision (fig. 143), or one in the form of figure 144.

The posterior surface of the joint is evidently the most eligible part to make a free opening, the large artery and nerves, with the exception of the ulnar, all lying in front—being separated, too, from the bones by the brachialis anticus muscle. The operation is accordingly always done on the dorsal aspect. The patient may be either laid on a table with his face downwards, or seated on a chair; the former position ensures greater steadiness on his part, and I have seen it most frequently preferred; but the latter I have myself selected,
as the operator can so move the arm as to enable him to inspect the ends of the bones more accurately than whilst the patient is kept on his face. I believe, however, the position of the body is of less moment than some seem to imagine, particularly since the introduction of anesthesia. Whichever attitude is fixed upon, the arm and fore-arm should be firmly held by an assistant; then a single incision of four, six, or eight inches in length, such as was originally proposed by Park, and has been recommended by Langenbeck, may be run along the back of the arm and fore-arm, or a crucial incision should be made directly over the olecranon; but if a free exposure of the parts be deemed requisite, the incision (fig. 144), in the shape of the letter H, represented above, which is similar in outline to that made by Moreau in his first operation, should be selected. On raising the flaps, which should consist of the entire thickness of the skin, as well as the condensed and infiltrated cellular texture underneath, the olecranon process will be laid bare: in cutting on its inner margin, the ulnar nerve must be carefully preserved from injury, which can be best done by dissecting it out of its position behind the internal condyle at this stage of the operation, and holding it aside with a blunt hook during the future steps; the attachment of the triceps should next be divided, and the cutting forceps or saw should be used to separate the olecranon from the shaft of the ulna. The surgeon will thus be enabled to appreciate the condition of the articular surfaces more clearly than heretofore, and directed in his future steps by the apparent extent of disease. He may now, with the forceps, divide the remaining portion of the upper end of the ulna, the head of the radius, and whatever part of the humerus may seem eligible. In the adult the saw may be requisite for the latter purpose, but in the young patient there is no difficulty in effecting this object with the instrument recommended, and occasionally the gouge (fig. 17, p. 9) may be of service in scooping away small spots of carious surface which cannot be conveniently reached by either forceps or saw.

These portions of bone (fig. 145) have been preserved to show the piecemeal manner in which the operation may be accomplished. Indeed, in all instances I imagine it better to remove the diseased bones bit by bit in the manner just described than to isolate the parts so extensively as some have advised. One of the fragments is the olecranon, the other a portion of one of the condyles of the humerus, and both are in a state of caries.

The lateral ligaments must be cut through to allow the ends of the bones to be fairly turned out, and this had better be done at once; there is no necessity, however, for exposing such an extent of their shafts as was formerly deemed requisite, as the saw (p. 7) may be used with perfect case, without the presence of a broad spatula in front of the bone, as
has been recommended; indeed, the method of removing the diseased portions of bone here described seems to me to constitute a most important difference from that resorted to by Moreau, who, in separating the "enlarged and rough" end of the humerus, doubtless went far beyond the actual disease, and thus made the wound unnecessarily extensive and severe. The sketches of the parts removed by him, in my opinion, sufficiently indicate this, and I hold it to be of the utmost consequence, in the performance of this operation, to distinguish between caries and that enlarged and hardened condition of the bone in the immediate vicinity of this disease, which, though altered in structure, should be allowed to remain, whilst, to ensure success, the former must be taken away. Although in disease of the elbow-joint of old standing, it frequently happens that the swelling of the soft parts is very extensive, it by no means follows that the bones are affected in equal proportion; indeed, it most commonly appears that caries is limited to the articular surfaces or their immediate vicinity. Large portions of the shafts of the bones have been occasionally removed with success, and any such step is preferable to amputation.

Drawing 146 gives a beautiful representation of the ends of the bones of this articulation in a stage of caries. The cartilages have disappeared, and left the surfaces in the characteristic condition of this affection. The "enlarged and rough" extremities are likely enough to be mistaken for disease by those who are not familiar with such appearances, but the experienced surgeon can at once detect the difference, and the same individual knows that whilst in the thick and rough parts there is an excess of vitality, as it were (as evinced by the formation of new bone), there is the lowest amount of it on the surfaces which have been denuded of cartilage. In short, these (the latter) are the only parts absolutely requiring removal; but to facilitate this, and to make the surfaces in some measure level, so that they may come into tolerable apposition, and adhere by bone, or make a good false joint, it is advisable to remove some of the rough parts, although it is seldom necessary, for the mere excision of the caries, to go much beyond the articular surfaces.

The next drawing (fig. 147), I esteem as one of the most graphic in this volume. It is taken from a preparation of a diseased elbow in my collection at King's College, and may be considered as faithful a representation as any engraving will exhibit. The body, which has been added by the artist, may be supposed to be lying face downwards, or seated on a chair; the bend at the elbow is just such as may be seen in life, although at this stage of the operation the fore-
arm may be bent and twisted in all directions; the swollen state of the soft parts, and the enlargements of the ends of the bones are well displayed; marks of several small openings on the inner side of the joint, and the earious articular surfaces, are well made out. The shape of the incisions and flaps, and the ulnar nerve immediately behind the internal condyle, must also give clear illustration of what has been stated in previous pages; and I imagine that any one who has witnessed many of these operations, must admit the general accuracy of the representation. The joint is extensively diseased; in fact, it appeared so much so, that I deemed amputation advisable, and accordingly performed it, being afraid, from the exhausted condition of the patient, that he would not be so safe with such a wound as that requisite for excision; but I have seen the latter most successfully practised in limbs equally bad, and in the present day I should not hesitate to perform excision in such a ease in preference to amputation.

The accompanying sketches will further illustrate these observations. Figure 148 gives a very accurate representation of the appearance of

the arm of a boy who was under my care in King's College Hospital years ago. The local disease was more developed than in the instance above alluded to; yet, emboldened by what I had previously seen, I
performed excision, and the result is displayed in figure 149, a sketch from a cast taken some months after the wounds had firmly cicatrized.

*Fig. 149.*

The particulars of this case will be found in the first number of *The Medical Times and Gazette*, January, 1852, and I have special pleasure in stating that I have this year (1870) seen this patient in excellent health, with an arm and joint (false) little different from those on the other side.

*Fig. 150.*

Figure 150 is from a photograph of a case of this kind occurring subsequently to the above, and the result of resection here was equal to any I have seen.

During the performance of this operation, the humeral artery will not require to be compressed; and if the excision be done as above described, there is no danger of wounding this vessel in front of the elbow, as the brachialis muscle, lying between it and the joint, must be a sufficient protection in all instances where the knife is used with ordinary discretion.

Although, generally, the bleeding ceases ere the divided portions of bone are removed, one or two small vessels may require to be tied;
the edges of the wound must then be brought together and stitched, and the arm should, generally, be kept in a bent position during the remainder of the treatment. A stiff arm may probably be the result, but in most instances a new or false joint should be expected. In the early treatment after the operation, an angular leather or other splint should be worn on the under or inside of the arm, so as to keep it steady; but in the course of the first week and afterwards motion should be freely encouraged. Some considerable time may elapse ere the wound and sinuses finally close, but provided all the diseased bone is removed, cicatrization must ultimately occur, and by this time the patient's health will be perfectly restored.

Since the early edition of this work was published, a step in advance (as I consider it) has been made in regard to this department of surgery. Generally it has been considered an achievement if the surgeon could abbreviate the patient's sufferings by resection, and secure an ankylosis in the site of the incurable disease; but now the aim is to form a false joint, or, as it might be better called, a new joint in this locality. Instead, therefore, of keeping the parts quiet, with the view of securing ankylosis, it is now much the custom to move the parts freely throughout the treatment of the external wound, so as to produce a callous state of the ends of the bones, such as will terminate in movements so free as to make amends for the loss of the original joint. Even in instances where ankylosis has occurred after disease has been cured, or after accidents, such as luxation unreduced, a division of parts, or an actual excision may be effected with great advantage. I believe that we are indebted to Mr. Syme for suggesting this improvement on his favourite operation on the elbow, and I have much satisfaction in bearing testimony to its advantages. It is worth bearing in mind that in the first case of excision of this joint by Moreau, in 1797, "flexion of the fore-arm upon the arm was strong, firm, and steady," when seen in 1801. I am so much convinced of the advantages of a false or new joint in this locality after excision, that I now generally use an instrument, devised by Mr. Heath, formerly house-surgeon at King's College Hospital, which serves to prevent the bones coming into close contact, and yet permits of flexion and extension.

It is seldom that excision is required in any part of the shaft of the humerus; but should it ever be deemed necessary to expose any portion of this bone, there would be little difficulty or danger in doing so by making the incision on the posterior or outer surface of the arm, as in the operation for false joint already referred to. In such cases, however, it is possible that there may be some subsequent loss of power from division of numerous twigs. I have recently had under my care an instance of extensive necrosis of the humerus, wherein it was deemed necessary to make free incisions on the outer part of the arm. The musculo-spiral nerve was divided, I imagine, in the needful incisions, and the result has been paralysis of the extensor muscles of the fingers. My experience induces me to advise great caution in cutting near this nerve, for I have observed the evil effects of its division in several instances.
Here I have great pleasure in alluding to a case of excision in this locality, which I believe to be unique in surgery. In 1864 a woman, twenty-four years of age, came under my care at King’s College Hospital, with a firm tumour involving the whole thickness of the humerus, about the size of a large lemon, and about three inches above the elbow-joint. It had grown steadily for about two years, and in consequence of excessive pain, amputation had been recommended by one of the most competent authorities in London. But it was impossible to look otherwise than with pity on a fine hand and fore-arm. There seemed no malignancy, and therefore no hurry, and I advised delay, although I could not anticipate any other step should the tumour increase and give further distress. It did increase, and a softening seemed to occur in the mass, so that movement could be detected, as if fracture had taken place. There now seemed necessity for action, and I resolved on a step which I had occasionally meditated in reference to tumours in long bones. Instead of amputation I proposed to remove the tumour by dividing the humerus above and below, — being encouraged to this step under a strong impression that the growth was not malignant. Figure 151 represents the appearance of the arm at the time of her admittance into the hospital. The operation was performed in February, 1865. The chief risk was that of opening the elbow-joint, owing to the proximity of the tumour. This was happily avoided however. The incisions were made on the sides and back part of the arm in the form of an H, and so close to the tumour, that besides the skin and muscles periosteum and bone only were divided. Figure 152 will give an idea of the thickened bone and fissure running across where it had softened and broken. One section of the preparation is in the Museum of King’s College, the other at the College of Surgeons. The wound healed kindly. There was no osseous union, and the limb if left alone dangled uselessly; but, by applying a leather case to keep the arm steady, the fore-arm, hand, and fingers at once became of much service. On a recent examination I find that she has laid the splint aside, and prefers using the hand as the servant of the left,
with which she does the most active work. She has often expressed thankfulness for the preservation of her hand, in which the power of flexion and extension seems almost perfect. This case was published in the Medical Times and Gazette of the 4th of March, 1865.

In many instances of injury or disease of the head of the humerus, the surgeon attempts to save the upper extremity by the performance of excision of this portion of the bone. In gun-shot injuries, when the soft parts are not extensively destroyed, the operation has been adopted with the most happy results; and it is now so frequent in civil practice, that it is justly esteemed one of the most legitimate and brilliant achievements of modern surgery. When the head of the bone is shattered into fragments, an excision extending four or five inches from the acromion, in a line with and through the fibres of the deltoid, as recommended by Larrey, in imitation of the original operation performed by White, will enable the surgeon to remove as much of the injured bone as may be required: the wound in a muscular subject will be narrow and deep, and although I have succeeded in removing fragments of necrosed and carious bones through such wounds,—in which, however, I did not open the capsule,—I give a decided preference to fresh incisions, whether the head of the bone is to be removed for gun-shot injury or for caries. These may sometimes be advantageously made by laying open sinuses, and the operator need not be prevented from doing so by any fear of the effects of dividing the deltoid extensively; but, as a general rule, I recommend the adoption of a plan similar to that originally followed by Morel. The patient being seated, or laid on his back, an incision should be made with a strong bistoury, commencing opposite the coracoid process, and ending about an inch behind and below the root of the acromion. It should be semilunar in shape, like the upper dotted line in the figure on page 300, exhibiting amputation at the shoulder on the right side; the extreme convexity should be about four inches under the acromion, and thus the greater portion of the deltoid will be included in this flap. In the drawing alluded to, the knife is represented as being about to be thrust in below the root of the acromion. On this side it will be most convenient to do so, especially if the surgeon stands a little in front of the patient, and on the left shoulder the wound may be made to commence as above directed. However, the operator may suit his own taste in these matters. The skin and deltoid being divided, the flap should be drawn upwards, a few touches of the knife being sufficient to separate the loose connexions of this muscle. A bold incision should next be made through the tendons attached to the tuberosities of the humerus, dividing them and the capsule at the same time to such an extent, as to permit the head of the bone being turned out by a slight twist. This part should then be laid hold of with the lion forceps by the surgeon, or an assistant, and held steady whilst the saw (p. 7) is used to separate as much as may be necessary. If the operation is done for a shattered bone, its head cannot be thrust out like the end of a lever, as thus directed; and therefore the surgeon must make use of his fingers or any convenient hook or forceps, such as that last named, to enable him to raise the fragments. The diseased or injured
portions being removed, the glenoid cavity should be carefully examined, and if disease be present, it should be scooped away with a gouge, or cut off with pliers shaped like those represented in figures 14 and 16 on page 9. The lower surface of the aeromion should also be examined and scraped, gouged, or the whole process removed, according to eireumstancées. In the first incision, the knife will possibly divide the cephalic vein, and some branches of the thoracic-acromialis: these, however, should give no trouble, and throughout the operation the only vessels interfered with are the posterior circume-flex and its branches, which will be cut in dividing the posterior margin of the deltoid. Ligatures will be required, and may be put on before the head of the bone is meddled with, or afterwards, as deemed most convenient,—the hemorrhage, in the interval being commanded by the finger of an assistant. All injured or diseased bone being removed, and the bleeding stanchèd, the flap should be laid down, and the edges stithed. When in bed the extremity should be conveniently placed on a pillow, and when out of bed should be carried in a sling until, as strength increases, it can be dispensed with. If matters go on favourably a false joint should be expected, with wonderfully free and vigorous movement, but though the part may ultimately be stiff, there will be such free play of the scapula and clavicle, and of the articulations below, that a very useful extremity remains. I have seen some admirable results from this operation, but, like other excisions, some judgment is required in discriminating the cases to which it is applicable.

In contemplating an operation of this kind previously to its performance, the surgeon ought not to limit himself to one mode of procedure; but should rather, trusting to his anatomical and manipulative skill, adapt his measures to the peculiarities of the case: he may make the flap above described more to the back part of the joint in one instance than in another; he may make a kind of square-shaped flap, thus (Fig. 153), one incision in front of the articulation, the other behind, both being united above by a transverse division of the deltoid a few lines below the aeromion. A flap, four inches in breadth and three in length, as was made by the elder Moreau, can then be turned down, or, by making the transverse incision below, the flap may be turned upwards. A \[\text{incision, as recommended by Sabatier, a }\] or lines thus, \[\text{in short, the surgeon has the option of cutting anywhere, and in any direction, over a most extensive surface, where he need not dread coming in contact with any large vessel or nerve,—the axillary plexus being so completely out of the course of all reasonable incisions, that if he is weak or ignorant enough to have a doubt on the} \]
latter subject, he will best display his remaining stock of wisdom by not interfering with the ease at all. Here my experience leads me to caution against cutting freely near the posterior margin of the deltoid. Division of the circumflex nerve is fatal to the subsequent action of the muscle.

Some time ago a case of disease of the head of the humerus came under my care in King's College Hospital, which I treated by a proceeding of an unusual, if not entirely novel, character. The patient, a healthy female, between twenty and thirty years of age, had suffered for several years from disease of the upper end of the humerus; an abscess had formed on the outer side of the shoulder, about the middle of the deltoid muscle, and a sinus, leading to bare bone was the result. The disease had been stationary for many months, and the arm was in a manner useless. The circumstances were such as to induce me to think of excision of the head of the bone. As there were no symptoms of disease in the articular surface, however, I thought it possible to remove the affected part by an operation, and yet preserve the joint. I laid open the sinus by an incision about three inches long in the course of the fibres of the deltoid, and thus made room to apply a gouge to scoop away the faulty portion of bone. It was found requisite to use the instrument more freely than had been anticipated; and

ere I was satisfied that the disease was completely removed, I had excavated a large portion of the head of the bone. The joint was happily left untouched. The wound was dressed with lint, and allowed to fill by granulations; the healing process was slow, but ultimately the opening closed, and the patient regained the complete use of her arm. Before commencing I had arranged that, in the event of its being found requisite to open the capsule, I should then adopt the ordinary proceeding for excision of the head of the bone.
It is seldom that the head or upper end of the humerus when affected with tumour is removed by local operation or excision, yet I believe that every now and then such a proceeding might be preferable to amputation of the limb at the shoulder-joint. Here (figs. 154 and 155) are representations of the right humerus with a large tumour developed in the head and tuberosities. Figure 154 is from a cast of the shoulder before amputation at that joint, and figure 155 is from a dried preparation of the tumour. Years ago, with less experience than I have now, I, in accordance with the rules of surgery, performed amputation, but in recent times I have felt remorse at having sacrificed such a hand and arm as are here represented (fig. 156). Were I to meet with such a case again I should be greatly disposed to give the patient a chance of having the greater part of the arm preserved by removing the tumour by excision. There is no want of precedent for this practice as regards other bones. The cases referred to at page 266 are in point, and although the idea seems never to have struck any one, I consider that excisions of the condyles of the lower jaw are quite in harmony with this doctrine. The arm might be loose and dangling, but it would be superior to any artificial one, particularly as regards the elbow, fore-arm, and hand.

Since the last edition, these views have been realized on the living body. In 1860, and again in 1862, Mr. Syme removed the head of the humerus, in both instances for comparatively small growths. In the same year Dr. H. N. Bennett, of Bridgeport, Connecticut, performed a similar operation, which was reported in the American Journal of Medical Science, October, 1863. Sixteen months after the operation the condition of the patient was most satisfactory: it was reported that he could "plant corn as fast as any man." The removal included about five inches of the humerus, and the tumour was about thirteen inches in circumference. This case makes me regret the more that I did not exercise the same skill and ingenuity in the case above referred to. The tumour here was also about thirteen inches in circumference, and from the subsequent history of prolonged life and health, there can be no doubt that the growth was simple in character. A most interesting paper on "Excision of the head and upper third of the humerus for bony tumours," has been published by Professor Blackman of Cincinnati, in the first number of the American
Practitioner, January, 1870, containing much doctrine of which I greatly approve.

It will seldom happen that excisions are required in either scapula or clavicle. In the latter bone I have referred elsewhere (p. 241) to an instance in which, after a compound fracture, I removed various loose fragments. Cases of caries or necrosis of the acromion process or spine of the bone are occasionally met with, and the diseased portions may be readily removed with a gouge. I have frequently done so with the best results, and in two instances have successfully taken away the whole of the acromion process,—detaching one end of it from the clavicle with the knife, and the other from the rest of the bone by means of the cutting pliers. The external incisions were made through the sinuses which were present in these cases.

In 1819 Mr. Liston removed a vascular growth situated chiefly below the transverse spine of the scapula, and with it three-fourths of the bone. The bleeding is described as having been frightful. Similar operations have been repeated by other surgeons. The scapula has even been more extensively attacked than in this case—the whole bone having been removed, and the superior extremity with it. Such an operation was done in 1808 by Mr. Cumming, in 1830 by Gaetani Bey, and by Larrey in 1838, all for gun-shot injury, and a somewhat similar operation, after injuries from machinery, has been recorded by Mr. Heron Watson in the Edinburgh Medical Journal for August, 1869. Amputation at the shoulder-joint was first performed, and immediately thereafter the scapula was taken away, with a portion of the acromion.

In 1842, Rigaud of Strasbourg removed the scapula, with the outer extremity of the clavicle, eight months after amputation at the shoulder-joint. In two months the wound healed, and two years afterwards the patient remained well. In February, 1847, I operated in a somewhat similar case at King's College Hospital. The particulars were afterwards published in the Transactions of the Royal Medical and Chirurgical Society for the same year. Amputation at the shoulder-joint had been performed three years before for caries. When I first saw the patient he was evidently sinking under continued irritation resulting from caries
of various portions of the scapula, and chronic inflammation of the whole bone and of the surrounding tissues. My friend Mr. Barker, of Wantage, having the opinion that removal of the bone might save the man's life, placed him under my care with that view, and the accompanying figure (157), is taken from a cast made prior to the operation. The rest of the body was much emaciated, but the shoulder appeared as round and plump as in health. There were ten or twelve different openings on the skin leading to bare bone. Some of these openings led to the outer end of the clavicle, and it was resolved that in removing the scapula a portion of this bone should be taken away at the same time. The operation was one of the earliest of magnitude done in this country under the influence of ether. The diseased parts were removed through incisions on the surface, indicated by the black lines on the figure. The upper end of the long perpendicular wound was made first, to permit the division of the clavicle, about two inches from its outer extremity; the cross cut along the spine of the scapula was next made, and when the lower part of the perpendicular wound was completed, the triangular portions of skin were raised from the back of the bone; then the soft tissues in front of the perpendicular line were dissected forwards, when, by dividing the various muscles connecting the scapula to the trunk, the mass was separated from the body. Care was taken that the tissues in the axilla should be last interfered with, and thus there was less hemorrhage than there might otherwise have been: the axillary artery, which had remained patent to near the cicatrix of the original operation, was divided at the last stroke of the knife, but with due precaution not more than four ounces of blood was lost. There was so much chronic induration and thickening of the muscles lying upon the scapula that they were all removed with the bone. The recovery was slow, owing probably to the exhausted state of the patient before the operation. He, however, progressed favourably, without a bad symptom, and ultimately got into excellent health. I have recently heard that he continues in this comfortable condition. The scapula, which is now in the Museum of King's College, was macerated, and presents such an appearance as is indicated in the accompanying drawing (fig. 158).
The separate sketch represents the end of the clavicle, which was removed at the same time.

Sketch 159 was taken from this patient in 1864, who was well and hearty at that date, and is now (1870), allowing for the difference of twenty-three years, in equally good health.

In 1855 the entire scapula was removed by Langenbeck from a boy twelve years of age, the rest of the extremity being left. On the 18th September, 1856, Mr. Syme removed the whole scapula from a female seventy years of age, for tumour, involving the greater portion of the bone, the extremity otherwise being left untouched. The patient made a fair recovery considering her period of life, and had a very tolerable use of the upper extremity. She got into weak health, however, in November, and died on the 1st of December the same year. Mr. Syme read an account of the case before the Royal Medico-Chirurgical Society, 24th February, 1857.

Since the last edition of this work, this operation has been successfully repeated by Mr. Jones, of Jersey, Mr. Syme and myself, and Mr. George Pollock, and in another work* I have ventured to call it the *ne plus ultra* of conservative surgery. I am still of that opinion, for although bolder deeds have been done in removing the whole upper extremity and scapula at the same time, the conservatism of leaving the healthy arm, whilst removing the diseased scapula, is, in my estimation, the highest reach in that department to which I have given the name, and to which much of the labours of my life has been devoted.

This figure (160) is from a photograph of Mr. Jones, of Jersey's, case, and an illustration even more graphic (fig. 161) has been given by Mr. Syme in an Essay of his on this subject, published after the operations above referred to were performed.

Incisions for these operations must be regulated by the shape of the parts and other circumstances, and must be grounded on the anatomical, as also the mechanical, knowledge of the surgeon. In taking away the scapula whilst leaving the arm, I strongly recommend freeing and

* Lectures on the Progress of Anatomy and Surgery during the nineteenth century, at the College of Surgeons, 1864.
isolating the posterior and other margins before disarticulating, as much blood will thereby be saved.

Removal of portions of the clavicle is occasionally required. The instance referred to at page 241 is an example of the kind. There the proceeding was very simple, as the exfoliations were lying loose, and could easily be reached by enlarging the sinuses. Besides, the main thickness of the bone was entire and did not require to be touched. But sometimes the whole thickness of the bone is so involved as to necessitate its division in the accomplishment of resection. Cases requiring this are comparatively rare. In one instance I have had the pleasure of curing a protracted disease of the shoulder,—the true character of which was, for a long time, mistaken, by removing about an inch of the outer end of the bone between the acromion and the coraco-acromial ligaments. Here there was a deep carious ulcer, which had latterly been the principal source of mischief. The resection was easily effected through an opening made in the integument over the bone, about three inches in length. A Hey's saw, and the cutting forceps, sufficed for the division of the bone. Several years ago I watched the progress of a large abscess in the site of the inner half of the right clavicle, and in the course of some months the matter was discharged. I removed through an incision about an inch long, over the sternal articulations, nearly half of the bone in a state of
necrosis. The part was loose and isolated, and little force was required in extraction. New bone has since been formed, and now it would be impossible for a stranger to the facts to recognise that such an extent of disease and death had ever been present.

In 1827, Mott removed nearly the whole of the clavicle for an osteo-sarcoma, the size of a "couple of fists." The operation was said to have been most difficult, and upwards of forty ligatures were required. Dr. Mott had the politeness to inform me that the patient on whom this operation was done was seen by him in 1842, in excellent health. In 1832, Dr. Warren removed the whole of this bone for a similar disease, and the proceeding, though very formidable, was not attended with such hemorrhage as in Mott's case. A similar operation has been performed by Mr. Syme, who has subsequently remarked the facility in using the extremity after the wound was cured.

No set rules further than those of the common principles of surgery can be given for such operations. Those alluded to were evidently by the operators themselves deemed of the most formidable kind, and such, in my opinion, as should induce others, of less acknowledged reputation and experience, to weigh well all the circumstances before resorting to the use of the knife.

Doubtless in all such proceedings bleeding will be the most formidable cause of apprehension; the subclavian, internal jugular, and innominata veins, with their chief branches, should all be carefully avoided. The subclavian artery, too, and its branches, and even innominata, are in close proximity, whilst at the inner end of the bone the pleura is so near that it is not altogether free from danger. I imagine that, in any operation of the kind, it would be of great importance so to isolate the outer end of the bone, that it might be raised and used as a lever, to put the tissues at the inner extremity on the stretch. The least touch of the knife would then suffice for their division, and there would be less risk of wounding any important part with the point of the blade, than if the disease were left in situ, until nearly separated from its connexions.
AMPUTATION OF FINGERS.

CHAPTER VIII.

AMPUTATIONS.

Sometimes children are born with supernumerary fingers, and the surgeon's assistance may be required for their removal. If the part be firmly attached by bone or joint to another finger or to the hand itself, an operation similar to those described below will be necessary; but, in many instances, the offending part is attached merely to a narrow root of skin and cellular tissue. Some time ago I had two infants under my care, each having a fifth finger on both hands. The member was perfect throughout as regarded appearance—nail, phalanges, and joints all being present. Each was attached at the ulnar margin of the hand, a little above the root of the little finger, by a narrow neck of skin. There was no indication of tendons being present, and each part hung like a pendulous tumour. In one of these patients I removed the parts by passing a thread through the centre of the root and drawing a double noose sufficiently tight to strangle and cause it to drop away. In the other, I twisted the flexible root once round, laid the finger on the back of the hand, and retained it by a strap of plaster. The twist and the acute angle thus formed, together prevented the circulation, and so the part died and separated. Both of these cases were treated during the first few weeks of life, and judging from the slight annoyance which seemed to result from the proceedings, I should not hesitate in similar cases to recommend an early interference. I may refer to p. 257 for some additional observations on such cases.

When the phalanges of the fingers or thumb are the seat of incurable disease, amputation is generally performed, as excision of one of these bones, or a portion of it, would probably leave the remaining part of the member neither useful nor ornamental. Occasionally a small portion of carious or necrosed bone, or even the whole of a distant phalanx, may be removed with advantage. Here I beg particularly to refer to my remarks at pp. 199 and 200, and to caution the young surgeon against the too free use of the amputating knife in such cases, for I am satisfied that the most important part of a finger, viz., the soft tissues, may be saved by the simple removal or extraction of the dead portion of bone. I have seen an instance where all the phalanges and tendons had separated, and the skin and nail had remained: even this, I fancy, was better than amputation. This operation may be required for destruction of the soft parts, as well as of the bones,—as exemplified in the effects of various forms of inflammation, constituting whitlow, in the growth of tumours, and those external injuries to which the fingers are particularly exposed.

When a portion of a finger requires removal, the operation may be done either at a joint, or in the continuity of a phalanx. For the former, the best procedure, in my opinion, is to apply a narrow-bladed
scalpel or bistoury to one side; then, after cutting the skin and lateral ligament, by changing its position, to carry it into the joint behind, and through the articulation to the palmar aspect, where a sufficiency of soft parts must be left to cover the extremity of the bone, and unite readily with those on the posterior surface. The articular surface of the phalanx may be snipped off with the cutting forceps or left at the option of the surgeon.

Drawing 162 shows the first position of the bistoury, and the dotted lines point out the course of the incisions and the size of the flaps. Perhaps that in the palmar aspect may appear somewhat too large, but here, as in many other situations, it is seldom that the operator will find that he errs in leaving an excess of soft parts. The rag round the point of the finger may be supposed to cover the disease or injury for which the operation is required; but it has been exhibited for the additional purpose of adding force to my recommendation that the part had better always be thus enveloped, as the surgeon can then grasp it more readily with his left hand, and move it in such directions as will facilitate the progress of the knife.

If the operation is done between the articulations (that is, in the continuity of a phalanx), I recommend it to be performed in this way: a blade, similar to that exhibited in the drawings, should be pushed from one side of the finger to the other, close in front of the bone, and a flap made from this surface; a lunated incision should then be made across the posterior aspect down to the bone, when, after touching with the blade any tissue left undivided, the cutting forceps will complete the separation. The lunated incision may be first made if the surgeon so chooses.

Figure 163 shows the position of the knife after transfixion, and the lines exhibit the length of each flap. Here the point of the finger has been left uncovered, to illustrate further the recommendation in a preceding part of this page; for it must be apparent from the condition of the end of the finger, that the operator cannot have such a secure hold of it as when covered by a rag or surgeons' lint.
In either of these proceedings two arteries may require to be tied, though it is possible that no ligature shall be necessary, and in both a single stitch will suffice to keep the edges in contact.

Amputation of one or more of the phalanges may be done in a variety of ways, such as by a circular incision, by leaving two flaps, one on each side of the finger, or by cutting into the anterior part of the joint first; but after operating in almost all the different manners recommended by different surgeons, I seldom resort to any other than those above described, and of the two I generally give the preference to that in the phalanx between the joints, as in figure 163, for the sake of saving as much of the finger as possible.

When the whole finger is to be removed, the knife should be passed from one side of the joint to the other in this way: the back of the hand being towards the surgeon, the heel of the blade should be laid on the skin, about half an inch below the articulation, when by drawing it downwards, with a little pressure towards the joint, the lateral ligament will be reached and cut; the knife should next be carried across the articulation, and then towards the surface, so as to make a flap similar to the one already made on the opposite side. After the vessels have been secured (two will perhaps require to be tied) the opposite surfaces should be kept in apposition by means of a couple of stitches; a fold of lint should then be applied over the wound, and retained with a bandage carried round the hand, which will also have the effect of keeping the fingers still.

After the separation of the finger, as above described, I strongly recommend the removal of a portion of the metacarpal bone ere the margins of the wound are brought into contact. This can easily be done by carrying the point of the bistoury round the bone, about three-fourths of an inch above its extremity, and then dividing it with forceps.

The flaps, however, might be a little too long were the incision made so low down as in the operation just described, and those represented in this hand (fig. 164), will leave flaps sufficiently long to make an excellent cicatrix, provided the end of the metacarpal bone is removed; but if it is to be left, then the skin on each side of the joint should be retained of the full length above recommended.

Throughout my practice I have been in the habit of removing a portion of the metacarpal bone, in most cases requiring amputation of the whole finger, and I do not find that the operation is much more
troublesome or difficult. In no instance am I aware of bad effects having followed, such as injurious inflammation or deficiency of that degree of strength in the hand that might be expected to remain after amputation of a finger in the ordinary manner.

Figure 165 shows a hand after having been treated in this manner: and if it be contrasted with any example where the end of the metacarpal bone has been retained, I think that, in so far as appearance goes, the comparison is greatly in favour of the method which I generally pursue. In the hand from which this representation is taken, I was obliged to amputate the whole finger, in consequence of incurable disease; and as the young gentleman was somewhat particular about his appearance, it was satisfactory afterwards to find that he had not a fault to complain of. It is not reasonable to expect that after the performance of any of these operations the hand can be of the same

strength as it was previously; but certainly in this instance, as in many others treated in a similar manner, I have not heard any complaints on this score, and the patient, whose hand is now exhibited, was not aware, after the lapse of two years, of any material difference in the power of grasping with either organ. The owner of this hand has often told me that he was not conscious of any difference as to strength in one from the other.

If some care is not bestowed on the dressing, the fingers may be made to cross each other at the points; and sometimes, also, I have noticed that if too little bone was removed, a slight prominence on the back of the hand remained. Both of these conditions are observable in the hand (fig. 166) from which the middle finger was removed, but with too small a portion of the metacarpal bone. By applying the cutting forceps sufficiently high, and afterwards taking care to keep
the remaining fingers parallel with each other, these objections may be obviated.

I should wish it understood that, in thus removing the metacarpal bone, I do not at all interfere with the skin in the palm, and that the point of the knife is kept so close to the bone that I do not even divide the transverse ligament, as the supposed necessity for cutting this texture has by some been made an objection to this mode of operating, on the score that the hand is thereby weakened.

It will be observed that in these proceedings it is recommended that the finger should first be removed, and the small portion of bone afterwards; but if the operator chooses, both may be taken away at the same time. On the fore and little finger I generally prefer the latter mode, and in such cases the incision should be in the course of the lines exhibited in figure 167. For such an operation the point of the knife should be applied over the back and middle of the metacarpal bone, then carried downwards along the side and under surface of the joint, and up again to where it was first entered, as indicated by the dotted lines; after this the soft parts nearest the bone must be divided, and then the forceps may be used in such a manner as to cut the bone obliquely, so that there shall be no angular projection towards the skin. The wound need not be so near the middle of the hand as here exhibited, for if it is placed more between the finger and thumb, the cicatrix will be less conspicuous. This is an example of what, in modern surgical language, is called amputation by the oval method. Figure 168 represents the hand of one of my patients after such an operation.

Amputation of the little finger should be done in a manner similar to that on the fore-finger just described, and the hand will present such an appearance as that exhibited in figure 169, which may be considered as directly in contrast with figure 170, immediately following, where the end of the metacarpal bone has been preserved.
In the forc-finger, if the upper end of the metacarpal bone is sound, I should certainly make a point of saving it, for various reasons, which must be obvious to any one acquainted with the anatomy of the hand; in the little finger I should also feel inclined to save the upper end of the bone if it were in a healthy state; and in each instance, to lessen the chance of the extremity of the remaining portion being observable, I would cut it across obliquely as above-mentioned.

I hope it will not be imagined from the preceding recommendations that I am an advocate for unnecessary mutilation. In other parts of the extremity it is an object of importance with the surgeon to form what is called, in common language, a good stump; and my own opinion is that operations, such as have just been described, are well calculated to do so in this situation. There may, however, be many instances in which it might be advisable to leave the end of the metacarpal bone, and if it were sound this should be done. Not long ago I saw a baker, who had lost one of his fingers, and with whom, according to his own account, the breadth of the palm was of great consequence.

In proof of my anxiety not to remove more than is positively required, I must refer to this cut (fig. 171), which exhibits the stump I was enabled to make in an instance of gunshot injury of the hand, when even the two fingers which were ultimately preserved were in an almost hopeless condition. The bursting of a pistol caused extensive compound fracture and laceration in the thumb, fore, and middle fingers, and, in addition, the palm was most severely shattered. I resolved, nevertheless, to attempt saving the two fingers which were less seriously damaged. Accordingly, by making a transverse incision on the back of the hand, and another on the palm, both within an inch of the carpus, and then carrying the knife downwards in front and behind a little on the radial side of the ring finger, I managed, notwithstanding a subsequent severe attack of erysipelas, to save such an organ as is represented in the sketch. I have known even a single finger preserved with advantage, and the accompanying figure (172) shows an instance where the thumb was the only member which it was thought proper to leave.

If the flexor and extensor tendons still preserve a certain amount of influence, these remaining portions, though they be small, will be of
AMPUTATION OF FINGERS.

infinitely more service than any artificial substitute. For my part, I should say that such cures reflect greater credit on the surgeon, and the art which he professes, and, moreover, are a better cause for self-gratulation, than the more extensive mutilations which, from time to time, he feels himself obliged to inflict.

Occasionally it is absolutely necessary to remove either the whole or a large portion of the metacarpal bone, and both ingenuity and skill may be exhibited in some such cases. Thus, in the hand which is here represented (fig. 173), it was evident that the tumours (enchondroma is now the term) involved the metacarpal bone and first phalax of the fore-finger, but it was difficult to make sure that the disease was not also connected with the contiguous bone in the hand. Here I resolved to be guided by what should be ascertained during the progress of the operation; and in performing it, finding that the disease was limited to the fore-finger and its sustaining bone, I was enabled to preserve the rest of the hand, as represented in figure 174. The proceeding was accomplished much in the manner already described for removing the index finger.

The next drawing (fig. 175) exhibits a large tumour connected with the middle of the palm, and with the middle and ring-fingers. It is the largest of the kind I have seen; but we have the cast of a larger one in the Museum at King's College, and there is one of greater magnitude portrayed in the third volume of the quarto edition of John Bell's Surgery. Here I intended to remove both the affected fingers and their metacarpal bones, but the patient refused to submit to an operation, although he had come many miles for the purpose of having one performed.

It has fallen to my lot to see many such cases. The term spina ventosa has frequently been applied to them, but I have never seen an instance on the living body where there has been merely a large shell
of bone with a corresponding cavity within. The tumour has always appeared as a solid mass, connected with a phalanx or metacarpal bone. Sometimes there has been only one, occasionally several. Generally the whole thickness of the bone has been involved, the projection being greater on one side than the other. In rare cases a growth resembling these comes on the sheath of the tendons, and in one instance I found the usual condition in a phalanx on one finger, and a growth on the sheath of the flexor tendons on the contiguous finger. This is the only instance of the kind in which the patient complained of pain, and the amputation of the fingers gave entire relief. When such tumours are cut into immediately after the removal, they present a fibro-cartilaginous appearance throughout, with deposits of osseous substance here and there. The circumference of the tumour is always a tolerably well-defined shell of bone, thick near the phalanx, but thin elsewhere, especially when the tumour is large; and often at some particularly prominent points the osseous shell is deficient. In a macerated or dried specimen the shell alone remains, and gives an appearance like that here represented (fig. 176). In this tumour the fresh section gave the usual characters. The specimen here represented was dried without any previous maceration, and from the hollow in this preparation it may be perceived how much of such growth is so soft as to disappear by evaporation.

When two or more fingers require to be amputated at the same time, the metacarpal bones, if sound and covered by healthy parts, had better be left entire. Each finger may be taken off separately, lateral flaps being made; or, what will answer better, a transverse incision can be carried across the dorsal surface of each a little below the articulations; another may then be made in front; the lateral ligaments and other textures should next be cut through in any manner most convenient to the operator, and thus the parts may be removed one after the other.
Amputations of the thumb may be done in a similar manner to those of the fingers. If the two phalanges only require removal, the metacarpal bone should not be meddled with. This sketch (fig. 177) shows the outline of the incisions for the purpose of separating the two phalanges. The end of the metacarpal bone may be removed or not at choice.

In some instances the metacarpal bone is the only one diseased, and it becomes a question whether the whole thumb is to be sacrificed in such cases. The thumb is of such great utility, that it ought not to be removed on such considerations as might induce the removal of a finger. In saying this, I do not mean to imply that a finger even should be taken away without due consideration, and a just cause: I only wish it to be remembered, that the thumb is of incalculable advantage to the hand, and that therefore, if it can be preserved, even with diminished utility, it will be better to do so than to sacrifice it entirely. In corroboration of these remarks, I may state that I have seen extirpation of the metacarpal bone of this member performed, and the phalanges preserved: though the organ was far from being strong, still the patient (a female) could use the needle with tolerable facility not long afterwards: the appearance of the hand was less remarkable, and evinced slighter trace of mutilation, than if the thumb had been entirely removed. If an attempt were made to save a finger by excision of a diseased metacarpal bone (and there can be no doubt that such an attempt would succeed), the organ would really be of little service. There are other fingers to compensate, in some measure, the loss of one, but the loss of the thumb can never be supplied. Moreover, the thumb will be, in all likelihood, a much more powerful organ, after the extraction of its metacarpal bone, than the finger after a similar loss, as may be conjectured from the difference in length of the two, both in the remaining portions, and those that are taken away, as well as from the firmer cushion of soft parts that will remain from the ball of the thumb, than from the corresponding textures in the hand.

The metacarpal bone of the thumb may be removed through an incision on its radial margin, where the surgeon may avoid cutting either the extensor or flexor tendons. The distal extremity should first be detached from its connexions, when the bone can be used as a lever whilst separating it from the other parts. The radial artery will be endangered whilst cutting some of the fibres which bind the bone to the os trapezium.

When the thumb and metacarpal bone are to be removed, the
operation may be done by carrying a bistoury through the soft parts between the metacarpal bone and that of the fore-finger upwards, until it is arrested by the trapezium; then through the joint; and lastly, by cutting downwards, and forming a flap of the fleshy substance constituting the ball of the thumb. Figure 178 exhibits the bistoury in the first of its course, and the dotted line shows part of the incision outwards, this being formed after the end of the bone has been disarticulated.

By the method just described a cicatrix will be left on two sides of the stump, and on that account an oval amputation may be preferred. This proceeding may be done thus:—The point of the bistoury or scalpel should be laid on the skin on the radial side of the metacarpal bone at its junction with the carpus; it should then be carried straight down to within half an inch of the joint between this bone and the phalænx, when it should be taken in an oval direction round the lower part of the joint, so as to join the straight line above; the soft tissues should then be separated from the metacarpal bone, which, with the thumb, may be used as a lever to put the ligaments between it and the trapezium on the stretch, so that a few touches with the point of the knife may suffice for its separation. When the edges of such a wound are brought together there will be only one line of cicatrix, which perhaps constitutes the main feature of the oval amputation. Figure 177 shows the chief outlines of the external wound, with this difference, that they should be a little nearer the carpus. Long experience leads me now to state that these two last described operations have more of the dissecting-room characters than likely to be required in practice.

In all these operations, indeed in most others, in different parts of the body, though the cutting instrument is held in the right hand, the dexterous use of the left will be of infinite service. In amputation of a finger it will (as I have already stated with reference to the phalanges) be advantageous in most cases to wrap a bit of lint round it, so as to enable the surgeon to take a firm hold with the thumb and fore-finger of his left hand; when, by turning in a proper direction, he can throw the textures about to be cut so much upon the stretch, that the slightest touch of the knife will divide them; and in operating at a joint, unless the part intended to be removed be held to one side, it will scarcely be possible to pass a knife across without coming into contact with some point of cartilage or bone.
A common scalpel may be used for all the operations above described; but I almost invariably prefer a long, narrow, slender bistoury, the blade of which is about three inches in length, and less than a quarter in breadth at its widest part. It may be fixed in a common ebony shank, but for convenience I give the preference to the clasp bistoury, which shuts into its handle after the fashion of a pocket knife. The narrowness of the blade enables the operator to pass more rapidly across the joint, while its length permits him to shape the flaps with a freer sweep of his hand than when he uses the broader, shorter, and less elegant scalpel.

I cannot conclude these observations on amputations of the phalanges and fingers, without adverting to the greater facility of performing them on the living subject than on the dead. In the latter, the skin and other soft parts are usually so thin, that it requires great care, and even skill, to reserve sufficient flaps; whereas, in the former, the subcutaneous cushion of fat almost invariably gives a more favourable opportunity of preserving a better covering to the end of the bone; and in some cases (as in the thickening attending severe forms of whitlow, in which the whole or a part of the finger may require removal), the textures operated on may be so infiltrated with lymph, that a sufficient and very excellent stump can be reserved; though it must be remembered that such a condition renders it perhaps more troublesome to get into the joint, when this locality happens to be selected or required.

Amputation of the hand may be performed either at the articulation of the carpus with the fore-arm, or a little higher up, where the bones will require division with the saw. The first may be done in this way:—The hand being held in a horizontal position, with the back upwards, a scalpel, or, what is better, a large bistoury, such as is exhibited in the drawing 179, should be carried in a semilunar course down to the bones from one side of the wrist to the other, about one inch or more below the articulation; this flap should then be dissected up, and the posterior part of the joint opened: this and the future steps of the operation will be facilitated by bending the hand downwards, in the manner exhibited in the figure; the textures on each side of the wrist should next be cut through; and lastly, a flap, similar in size and shape to the one already made, should be preserved from the front. The lines of incision are marked out in the figure by the
dots below the wrist. The articular surface of the radius and the end of the ulna may be left or removed, in accordance with circumstances or the views of the surgeon.

In severe injuries of the hand requiring amputation, where a sufficiency of soft parts can be preserved to cover the end of the radius, this operation should be performed in preference to that higher up. Surgeons in this country have had but little experience of this proceeding, yet, considering the success which has attended amputation at the ankle-joint—a proceeding to which this may in some respects be deemed analogous—I should certainly wish the practice more frequently tried. I have myself had several most satisfactory operations of the kind; and this figure (180) represents one of the stumps on a middle-aged female.

Amputation in the fore-arm may be done in this way:—The elbow being slightly bent, and the hand placed in a state of pronation, a blade about six inches long should be passed from one side to the other behind (or above) the bones; it should then be carried downwards, so as to come through the tendons and skin about an inch and a half lower down; the flap thus formed being raised, the knife should next be passed across close in front of the bones, and carried obliquely downwards, when a second flap, similar in size and shape to that already made, will be formed: both of these should now be drawn slightly upwards, and after all the textures close upon the bones have been divided, the saw should be applied close to the roots of the flaps, and the part separated. If the latter instrument be well used, it is of little moment whether a single bone or both be cut at once. Some prefer to place the hand about to be removed in a state of supination, and to make the anterior flap first; others hold it between pronation and supination; but I have never been convinced that, under ordinary circumstances, any one of these three positions possesses such advantages over the other two, as should induce the surgeon to prefer it in all instances. It is of consequence, however, before transfixing, to observe the attitude in which the limb is actually placed, so as to avoid passing the knife between the bones,—a mistake I have seen happen.

The first position of the knife and the lines of incision are here shown (fig. 181). The posterior or upper flap, as thus exhibited, would be small in proportion to that below; but to avoid this, it is well in such a situation (indeed it is so in most parts of the extremities), to grasp the textures about to be transfixed, and to elevate them in such a manner as to keep more above the blade than can be done without this manœuvre. Such a proceeding is well exemplified in the drawing illustrative of amputation in the thigh with anterior and posterior flaps, and it will be found to facilitate transfixion, both the first and second time.

It will often be observed that the tendons hang out of the wound
AMPUTATION OF THE FORE-ARM.

after the flaps are brought into apposition, especially if the incisions have been made near the wrist. It may be advisable sometimes to

*Fig. 181.*

*Fig. 182.*

cut small portions of them away: occasionally I have known these projections slough, whilst at other times no inconvenience has resulted further than a slight difficulty at first in covering them with the skin.

Drawing 182 exhibits a stump made after the method above recommended. The sketch was taken from a patient whose hand I had to remove in consequence of a severe injury by machinery. The remaining part of the fore-arm is sufficiently long to admit of any kind of apparatus being applied as a substitute for the hand. It may be well on all occasions to keep the latter object in view: the part can scarcely be left too long for the attachment of anything of the kind, and the surgeon, if not on his guard, might inadvertently apply the knife so close upon the elbow, as to leave too short a portion below for the purpose in question.

Amputation, as above described, may be performed in the fore-arm with equal facility at any point between the wrist and the elbow; the radial and ulnar artery will each require a ligature, the interosseal arteries, particularly the anterior, will perhaps need to be tied, and possibly one or two more of a smaller size. The flaps may next be laid together, and retained by means of three or four stitches.

During the performance of these operations, the circulation must be arrested by compressing the humeral artery with the fingers or tourniquet, as recommended, and exhibited in the drawings at pages 24 and 26. In those at the wrist, the assistant who holds the arm may compress the two main arteries with the points of his fingers until ligatures are applied; and the like may be done, if required, during the minor proceedings on the hand and fingers.

It need scarcely be added, that the circular operation may be
applied in any part of the fore-arm: but considering the flat shape of
the member, and other circumstances referred to in the chapter on
Amputation, I should on all occasions give the flap method (particu-
larly that of Teale) the preference in this locality.

It will be observed that, in describing these different operations, I
do not enter into such minute details as some may expect; but I must
beg the reader, when he is not satisfied in these respects, occasionally
to refer to the introduction, where he may possibly find what he wants,
or, at all events, such general instructions appertaining to all opera-
tions, as to evince to him the propriety of not embodying them again
and again in other parts of the volume.

The fore-arm may be removed at its articulation with the humerus,
by making a semilunar incision through the soft texture on its anterior
and upper part obliquely towards the joint, which must then be cut
into, by dividing the brachialis anticus muscle and ligaments, when
by bending the limb backwards the bones may be so displaced as to
allow the knife (a long bistoury) to be carried across to the posterior
surface, where a flap must be left, which, with that in front, will cover
sufficiently the end of the humerus. In making the posterior flap, the
triceps must be cut through, or the olecranon process may be divided
with the saw or forceps, and left in the stump. The same vessel will
be cut across as in amputation a little lower down, and the same style
of dressing must be pursued.

The method here described is similar to that recommended by
Vacquier, who, however, removed the olecranon. Dupuytren trans-
fixed in front of the joint, and made the anterior wound in the same
manner as in the flap operation lower down. In the posterior flap he
sometimes left the olecranon, at others cut it away, and I agree with
Velpeau, that there seems no great advantage in preserving it. If any
portion of the fore-arm below the junction of the head of the radius
with the ulna could possibly be saved, I should prefer amputation
as described at p. 293 to this proceeding; if selecting the joint,
I should cut off the articular surface of the humerus including the
condyles.

Amputation above the elbow may be done in the following man-
er:—The patient being seated, or laid on a table, with the elbow
separated from the side, the humeral artery being secured by pressure,
as already described, the arm should be transfixed three inches above
the external condyle, with a knife about seven inches in length, which
should be carried obliquely downwards and forwards, so as to make
from the inner surface a semilunar flap between two and three inches
long: this should then be raised, when the soft parts on the opposite
side should be divided in the same manner to a similar extent; the
two flaps should now be drawn upwards, the knife then carried round
the bone, which should next be sawn through, and so the removal is
completed. The humeral artery being secured with a ligature, the
pressure above should be taken off, and every other branch that bleeds
freely tied; the flap should then be brought into contact, and kept in
apposition with four or five stitches.
Drawing 183 shows the position of the knife, after transfixion, and the dotted line the shape of the anterior or inner flap. The arm may either be straight, as exhibited in the figure, or slightly bent at the elbow, according to circumstances.

The humerus is covered by nearly an equal thickness of soft parts throughout its circumference, and it seems to me a matter of little moment from which side the flaps are taken.

The operation should be done in the lower third of the arm, if circumstances will permit; but the same instructions will answer for any part of its extent between the condyles of the humerus and its neck.

Figure 184 exhibits a stump on one of my patients at King's College Hospital. The flaps here were slightly different from those referred to in the description of the operation as given above; but the stump, in my opinion, could not have been better, from whichever side the soft parts had been preserved.

For a description of the circular operation in this situation, I may refer to page 190, and shall here only state to those who prefer this proceeding, that the arm, in my opinion, presents the best part of the upper extremity for the application of such a method.

In performing amputation of the arm, the surgeon may stand on either side he chooses, or that may be most convenient. I generally prefer the outside, and, for reasons stated in my observations on amputation in the thigh, commonly make the inner flap first; but on neither of these points do I consider it imperative to adhere to any single rule.

Before the young surgeon decides on amputation at the shoulder-joint, I must beg him to refer to my observations on excision at this articulation. If he has it in his power to make a reasonable attempt to save the
extremity, he ought of course to do so; but it often happens that he cannot do otherwise than adopt this last of all resources. Extensive injuries, by machinery or otherwise, phlegmonous erysipelas, gangrene, growths in the soft parts or in the humerus, caries or necrosis of this bone, may each necessitate amputation at the shoulder-joint. Fortunately it is an operation so easy in its performance, and at the same time comparatively, in reference to its magnitude, so safe in its results, that, under ordinary circumstances, when it is imperatively demanded, the surgeon may resort to it with the sanguine hope of a speedy and permanent recovery for the patient.

Supposing the joint to be in a tolerably natural condition, and that the surgeon prefers a printed authority to that which should be his legitimate guide—a knowledge of anatomy—he has an extensive field to choose from. Between twenty and thirty different methods have been recorded, not one of which can be clearly understood without a competent anatomical knowledge. The effort of distinguishing the minute differences between any two or three of these plans actually requires as much study as does the anatomy of the joint itself, whilst the knowledge acquired in the one pursuit is of incalculably less value than the other. Few surgeons, in the course of extensive practice, meet with many occasions for the performance of this operation; but, on the other hand, the necessity for an acquaintance with the physical structure of the shoulder is in a manner paramount. I do not mean by these remarks to discourage the study of the opinions and proceedings of many who are justly considered authorities on such matters; but, as it is not within the compass of this work to describe, or allude to, all that has been said or done in surgery, or to point out the trifling shades of difference in the practice of twenty or thirty individuals,—each of whom, be it remarked, is an authority perhaps equal to any other,—I shall rest satisfied with describing two methods which I have myself resorted to on the living body, after having given to most of the others a fair consideration and trial on the subject.

If the left arm is to be removed, the patient may be seated, but the position will be better if he is placed on a firm table, with the shoulder a little elevated and projected beyond its margin. The surgeon, standing on the patient's left side, should then lay hold of the arm a little above the elbow, and move it from the side and slightly backwards. A sharp-pointed amputating knife, seven or eight inches in length, held in the right hand, should then be pushed through the skin in the armpit, immediately in front of the tendons of the latissimus dorsi and teres major muscles, and carried upwards and obliquely forwards, until its point protrudes a little in front of the extremity of the acromion: during this movement, a good anatomist, with a dexterous hand, may actually open the capsule behind, by adroitly touching the tendons of the teres minor and infra-spinatus; but there is some danger of breaking the point of the instrument against the humerus in this attempt, and the operator may rest contented with
cutting as close to the joint as safety in this respect will permit. With whatever object the thrust is intended, it will be greatly facilitated by moving the elbow outwards and upwards; indeed, unless this be attended to, there is every chance of the point of the knife appearing through the skin long before it has reached the extremity of the acromion: still keeping the arm in the attitude last mentioned, the knife should be thrust up to its heel, and then carried, with a sawing motion, downwards, backwards, and outwards (i.e., towards the surgeon), so as to make a flap four or five inches in length, formed chiefly of the posterior part of the deltoid with the tendons of the latissimus dorsi and teres major, and the skin; this flap being raised by an assistant, the point of the knife should be used to open completely the posterior and upper part of the joint by a thorough division of the teres minor, infra-spinatus, supra-spinatus, capsule, and long head of the biceps; and to facilitate these steps, the elbow should now be carried in front of the chest, and the head of the bone pushed backwards. When the textures are sufficiently divided, the same movement will cause the luxation of the articular surface: the knife should then be passed in front of the bone, and carried downwards and forwards to form a flap about the same length as the other, by dividing the subscapularis, the remaining portion of the capsule, long head of the triceps, short head of the biceps, coraco-brachialis, front part of the deltoid, pectoralis major, vessels, nerves, and skin of the axilla and fore-part of the shoulder. In the last movements of the knife, the axillary vessels must be divided; and, to restrain hemorrhage, an assistant, at this period of the operation, should grasp the soft parts in the axilla. As soon as the arm is detached, a ligature should be placed on the main artery, the subscapular, and any other which may continue to bleed. The edges of the wound should then be brought in contact, and the line of union will be nearly perpendicular, the flaps being posterior and anterior.

Figure 185 illustrates this description. The knife (which, in my opinion, the artist has represented a little too long) has transfixed the shoulder, and the dotted line shows the size of the posterior flap, which, where the tissues are in abundance, may be made of any reasonable size and length the surgeon chooses.

This operation is nearly similar to the mode proposed by Lisfranc,
and may be varied in different ways. The point of the knife need not be entered so low: in which ease it may be pushed further forwards, and an upper flap, consisting chiefly of the deltoid, may be first formed. Then, to make sure of having this flap (made in either way) of the largest possible size, an assistant may be directed to grasp and raise the deltoid, whilst the parts are being transfixed, and, unless the surgeon has great power in his left hand, it may be as well that he should, at the first, intrust the management of the arm to an assistant; for, when it is held by another's aid, he can use his own hand in assisting to get the head of the bone out of its socket, so as to allow the knife to be applied in front. On the dead subject, or in an arm emaciated by disease, there is little trouble in elevating the bone; but if the arm be weighty, and the subject muscular, as is often the ease in severe injuries necessitating this operation, the foreible manner in which it is drawn to the side, by the action of those muscles which remain after the first flap is formed, is really surprising; and unless the surgeon be himself possessed of equivalent energy, he will have great difficulty in counteracting the combined opposition of weight and muscular action. Under chloroform such observations will not be applicable.

On the right side I have operated in this way:—The patient has been laid on a table, and, standing in front of him, I have with a stout clasp bistoury made a semilunar incision from a little behind the root of the acromion towards the coracoid process, and thus made a flap from the skin and deltoid, similar to that described at page 274 for excision of the head of the bone: this being raised, I have opened the joint from above, and preserved another flap from the remaining parts below the bone; and here, also, before dividing the axillary artery, I have desired an assistant to seize the vessel above. The movements of the humerus were regulated by holding the arm with the left hand. Figure 186 makes the above description more easily understood: the point of the knife should, however, be a little higher up.

For my own part, I should be as well content to use a bistoury for these operations, as the more imposing-looking amputating knife; but with such an instrument the first flap on the
left shoulder would be made by cutting from the skin towards the joint. There are few, however, who would not prefer a long knife, as it may be used on the right shoulder as well as on the left. The operator may either divide the structures, as above directed, from the skin towards the joint, or transfix immediately below the aeromion, as was done by Dupuytren, introducing the knife either in front of the joint (at the coracoid process) or behind it (at the root of the aeromion), according to the side on which he stands, and cut his way outwards. But I fear that already such operations may appear sufficiently complicated, even by my brief allusions to some of the various modifications and alterations which have been proposed from the time of Le Dran to the present day.

It will be observed that on the left side I have recommended lateral flaps, and on the right horizontal. A good anatomist would, however, have no difficulty in reversing these, that is, making lateral flaps on the right and horizontal on the left. He can scarcely err in preserving sufficient covering to form a good stump in either or in any way, and his chief anxiety will probably be with reference to the axillary artery. It is customary to desire an assistant to compress the subelavian above the clavicle, as it passes over the first rib, by means of his fingers or thumb, or with the end of a good-sized key covered with a pad of lint. However, I would not have the operator trust too much to this plan. In most of the instances where I have seen it pursued—indeed, I may say in all, I have observed it fail. It is certainly very easy to compress the subelavian in this situation, in every properly-formed person, when the body is at rest; but violent muscular movements during amputation make a vast difference: the clavicle and shoulder are almost invariably drawn upwards, and the pressure then is uncertain. These observations may now, since the introduction of anaesthesia, be taken with some modification. I have known a surgeon blinded for an instant with the first gush of blood from the axillary artery after its division in amputation,—at a time, too, when he expected that the subelavian was commanded. So sceptical am I as to the utility of this practice, that I feel almost inclined to say that it is worse than useless: the pressure (which is usually more energetic than there is any occasion for), provided it be properly applied, is often attended with considerable pain; but that being brief, and of little moment in comparison with the object in view, need form no valid objection. An assistant, however, who might be otherwise and better employed, is thus lost, as it were, and he is much in the way of those who have command of the flaps. Nevertheless these observations, probably most of my readers will still consider it a safe and almost necessary precaution; I cannot say that I disentenace it altogether myself; but I hope that what has been stated will show the propriety, possibly advantage, of grasping the vessel in the axilla, immediately above where it is to be divided.

With flaps, such as have been described, for the left shoulder, the stump should be similar to that represented in drawing 187, taken
from the person of a young man, whose arm I removed at the articulation, in consequence of a severe railway injury.

I think it of consequence to caution the young surgeon against expecting a very handsome flap, from any part of the circumference of the joint, more particularly from the axilla: here the surface is so irregular, that the soft parts must invariably be more or less puckered at first; but this need cause no annoyance; nor must he imagine that, in consequence, the operation has been improperly performed. By attention to the dressing, the stump will speedily assume the resemblance of the figure; all projections and puckers will disappear, and a uniformly smooth surface will be the result. It will be observed that the acromion projects considerably; but, so far as I have seen in these stumps, it is productive of no inconvenience. Were this the case, it might easily be removed, with a portion of the clavicle also; but this, I think, should not be done, unless it is positively required, as the deficiency of breadth of shoulder, already so conspicuous, would thereby be rendered more apparent.

Occasionally in amputations of the shoulder-joint it is requisite to remove parts of the clavicle and acromion, and probably more or less of the glenoid cavity or body of the scapula. The cases referred to at p. 278, where Cumming, Gaetani Bey and others removed the whole scapula immediately after amputation at this joint, are examples of the kind. I must say, however, that I can scarcely imagine any case of compound fracture of the scapula where removal of the whole of that bone would be justifiable as a primary proceeding. No certain rules can be laid down for the performance of these additional steps, and the operator must therefore be guided by the nature and peculiarities of each case, and by the knowledge which he may possess of the relative anatomy. The celebrated instance recorded by Cheselden, of Wood, the miller, who had his right arm and scapula torn off by machinery, and several of a similar kind which have been seen and recorded by Carmichael, Dorsay, and others, have exhibited the wonderful powers of nature in sustaining life, even after such frightful and extensive mutilations. Many years ago, during my connexion with the Royal Infirmary in Edinburgh, a boy about thirteen years old came under the care of Mr.
Lizars, with the extremity, scapula, and one-half of the clavicle, torn off by machinery; the skin on the side being also extensively removed. The axillary vessels and nerves hung loosely from the wound, but the bleeding was inconsiderable, the main artery being stretched, lacerated, and filled with clots. There was no shock; a single ligature was placed on the subclavian, immediately outside of the scaleni, where it pulsed, and contained fluid blood; the skin from before and behind was drawn as well over the wound as its condition would permit, and a rapid recovery ensued. A case similar in almost every respect has been recorded in Cormack's London and Edinburgh Monthly Journal (Feb. 1845), by Dr. King, of Glasgow.

In the museum at King's College there is a preparation from which the annexed figure (188) was taken. The patient, a lad fourteen years of age, was under the care of Mr. Cartwright, of the Middlesex Hospital, and made a good recovery.

So far as the mere shock produced on the system by operations for removal of so large a portion of the frame is to be taken into account, the surgeon may be amply justified in resorting to their performance; but it behoves him to consider well the nature of the case, before he proceeds to use the knife. It may be requisite, on some of these occasions, first to amputate at the shoulder-joint, and afterwards proceed with the removal of damaged portions of bone; or the surgeon may possibly make a laudable attempt to save the extremity, by operating on clavicle or scapula, as the case may demand; and it is on such occasions as these that forethought and presence of mind are of so much importance.

In 1808, Mr. Cumming removed the whole of the scapula, with the upper extremity, in a case of gun-shot injury. In 1830, Gaetani Bey, at Cairo, performed a similar operation (reserving, however, one-half of the clavicle), in a boy of fourteen years of age. The case was one of extensive injury: after amputation at the glenoid cavity, the scapula, being shattered, was cut away, and then the clavicle, being found to
project too much, was partially removed. The patient made a good recovery.

In the descriptions of amputation at the shoulder-joint above given, I have supposed the parts around to be in a natural condition; but it will be apparent that on all occasions the two methods especially mentioned cannot be put into execution. In gun-shot injury of the shaft of the humerus, or in compound fractures occurring in civil practice, the bone cannot be used as a lever, by grasping it immediately above the elbow; and under these circumstances the operator must raise or pull the upper fragment out of the way, in any manner most convenient. In such examples he ought always to reserve his left hand free, so that after the first flap is raised, he may be enabled to use it to the best advantage in disarticulating the head of the bone. On certain occasions, when the soft parts are much injured, some ingenuity may be requisite to preserve a sufficiency of textures to form a good covering to the glenoid cavity, and in such examples the removal of the acromion may, possibly, be advantageous; but the skin in front, behind, and below the armpit is usually so extensible, that however limited the flaps may be, I should not fear that a good stump would be the result. The best proof I can give on this subject is the case related at pp. 301 and 302, where the arm was torn off at the shoulder, in which although the loss of skin was so great as to expose a large extent of the serratus magnus muscle, the cicatrix ultimately appeared very small. In amputating at the shoulder, too, for large tumours in the humerus, close upon or extending to the joint, the surgeon must so divide the soft parts as to clear sufficient space to dissect out the diseased mass, and leave sufficient healthy tissues to form a proper stump. The common catlin will not be available on such occasions, as the operation partakes more of the character of a dissection for the removal of a large tumour than an amputation. A scalpel or bistoury will be the most efficient instrument. For my own part, I should prefer the latter; but I have seen a very large tumour of the kind alluded to, with the whole arm, most successfully amputated with the common scalpel. In this instance, the surgeon (Mr. Syme), in a very early stage of the proceedings, placed a ligature on the axillary artery; but in a similar operation, occurring in my own practice, I preferred disarticulating first, and dividing the soft parts in the axilla in the last movements with the knife.

In further elucidation of the subjects referred to in these latter pages, I may call attention to my concluding remarks on excisions in this locality contained in the previous chapter.

Since the last edition of this work, events have occurred in surgery which induce me to put on record my opinion that we may now reckon an amputation nearer the body than the shoulder-joint among the legitimate operations in surgery. In addition to the cases of removal of the scapula and part or whole of the clavicle, referred to at p. 278, many instances have been put on record where the surgeon has planned the removal of the upper extremity, including part or whole of the clavicle en masse. In gun-shot or machinery damage,
the parts may lie so invitingly, mangled and loose, that the readiest thought of the surgeon might be to remove them for the sake of having a clean incised wound; but the removal of all, for disease and tumours involving all, seems to me a more daring flight in practical surgery. To McLellan, of America, we are indebted for the realization of such an idea in 1838; and again, in 1845, another of our transatlantic brethren, Mussey, demonstrated successfully a similar process. Some seven cases or more of a like kind have subsequently been laid before the profession, and two of them have occurred in my own practice. One in a middle-aged man proved unsuccessful, probably from shock; but the other, in a girl twenty years old, resulted in the best that could be desired. In this instance one-half of the scapula had, some months before, been removed for a tumour of apparently benign character; but new growth, first in the axillary glands, and then in the surrounding tissues, seemed to indicate malignancy. Yet there was so much sound tissue to spare, and such apparent constitutional health, that I was tempted to give this girl a chance for life by removing all the diseased mass and arm at the same time. This was accordingly done, and figure 189 shows the extremity and proportionate size of the diseased mass, which involved the remaining portion of the scapula, the outer end of the clavicle, head of the humerus, and tissues in the axilla. The patient, having youth on her side, made an excellent recovery, and although I had a strong impression that the disease would soon return, she has enjoyed perfect health ever since. Figure 190 gives her appearance four years after the operation.

Such operations must be planned in accordance with the shape and size of the tumour. I fancy that the front and back flaps will probably be the most appropriate, and before these are made I recommend that the clavicle be sawn through about the middle or nearer the sternum. The extremity and tumour will then be more moveable, and the knife can be more readily applied. It is not likely that the inner end of the clavicle will be involved in disease, and there must be less danger if the parts attached to it and in its immediate vicinity are not divided or disturbed. By dividing the clavicle through a short incision in the skin over it, as a preliminary step, there will be no such
delay in dealing with the bleeding from such immense wounds as the flaps involve, as if the bone had to be cut across in the latter part of the operation; and in addition, I imagine that by the early division suggested, compression may be more readily applied to the subclavian artery over the first rib. In both of the operations which I performed, I grasped the main artery with strong necrosis forceps, the blades of which were covered for the purpose with soft leather. For many interesting particulars regarding these and similar cases, I may refer to the Lancet of 25th November, 1865, and 2nd November, 1867. In the "Mirrors" of these dates in that journal, in the essay by Mr. Heron Watson already alluded to, and particularly in an elaborate essay on Excision of the Entire Scapula, by Dr. Rogers, of New York, published in the American Journal of the Medical Sciences for 1868, the key to most of our knowledge on such exciting subjects will be found.

In concluding this chapter on amputation in the upper extremity, I feel justified by experience in stating that, in my opinion, most authors on such subjects have been far too precise in their injunctions as to shape, length, and thickness of flaps or coverings. I agree cordially with Mr. Teale's views as to keeping the nerves and vessels from pressure, and in having the cicatrix away from the part likely to be most exposed; but it seems to me of little consequence from what side the coverings are reserved or how they may be shaped, provided that the end of a bone be fully covered with tissue which glides freely upon it.
PART III.

OF THE INFERIOR EXTREMITY.

CHAPTER I.

SURGERY OF THE LOWER EXTREMITY.

In accordance with the arrangement of the section on the upper extremity, I devote a preliminary chapter to a sketch of the surgery of the lower limb.

A severe injury of the foot usually produces more serious influence on the system than a corresponding wound in the hand, probably from the comparative magnitude of the part. A reservation to this general rule may, however, be made as regards the toes, which, with the exception of the great one, bear so small a proportion in size to the fingers, that perhaps of two injuries of corresponding magnitude, that in the toe would be least as regards its effects on the system, from the comparative smallness of the toe. To counterbalance this, however, the extreme distance of the lesion from the centre of circulation, may be attended with injurious influence on the reparative action needful for a cure.

Although, in the chapter on the Surgery of the Upper Extremity, I have referred to the loss of a foot as being of less importance than that of a hand, certain exceptions may readily be admitted to this view, and, at any rate, no consideration of the kind could justify carelessness as to the conservation of even the smallest portion of so important a member. Happily, a strong feeling prevails among surgeons to this effect, and where parts of the foot are irrevocably damaged by injury or disease, these are often removed with the favourable result of saving a useful remaining portion. Indeed, it appears to me that surgeons have actually displayed more ingenuity in saving portions of the foot than of the hand. There are no operations on the hand equal in reputation to that of Hey or of Chopart on the foot; none equivalent to removal of the astragalus in luxation of that bone; or to compare with partial excisions occasionally performed in the tarsus; and none equivalent to resection of the diseased cuboid, astragalus, or calcaneum. Cases illustrative of the advantages of such operations will be referred to in future chapters, which will attest the anxiety, as well as the success of surgeons, in saving useful portions of this important part of the lower limb.
Injuries of the lower extremity, when at all severe in character, are followed with more inconvenience than of the upper extremity, as they involve the necessity for confinement to the house and the horizontal position.

The naked foot being, in civilized life, so little exposed in comparison with the hand, there are consequently fewer examples of poisoned wounds. Whitlow, so common in the fingers, may be said to be never present in the toes. In the great toe, it not infrequently happens that the nail, at one or both margins, grows so into the soft tissue, that it causes ulceration, and possibly an exuberance of granulation, attended by suppuration. Such a condition is analogous to that referred to at p. 197, under the name of onychia maligna. It is productive of much annoyance and pain—often causing lameness, and if it assumes a chronic state, the end of the toe, both soft parts and bone, gets into a permanently enlarged and inflamed condition, which incapacitates the individuals from occupation on foot. This state, if not improved or cured by paring the offending edge, can only be effectually dealt with by cutting a portion of the nail from the matrix, in the manner afterwards detailed, or by separation of both nail and matrix. I have seen the end of the toe so much enlarged in such a case, that amputation was deemed the best mode of treatment.

The peculiar inflammation constituting ehlblain is more conspicuous in the feet than in the hands, and the severer forms attended by sloughing and ulceration are seen only in the feet. The proper treatment in such cases is detailed elsewhere. Slight abrasions from shoes, accidental and trivial injuries when the feet are naked, or injuries inflicted by the surgeon, are occasionally followed by inflammation of absorbents, which may be traced as small red lines in the skin, more or less conspicuous, as high as the pelvis. Such cases are usually attended by considerable sympathetic fever; but it is rare for any great mischief to befal. Abscess at one or more points may ensue, but more frequently the inflammation subsides under the ordinary course of practice. The glands in the groin, like those in the axilla, sympathize in such cases, and troublesome buboes and suppuration may ensue.

Although the condition termed whitlow, is not recognised in the toes, yet the tissues here suffer as readily from destructive inflammation as those of the fingers, and abscesses in the sole of the foot are likely to be attended with an amount of suffering as great as in similar conditions in the palm of the hand. This is especially observable in the instances of suppuration which occur under the aponeurosis, and where the matter finds its way slowly to the surface. In such cases, a deep incision, made at an early period, may avert much suffering.

While it is rare to see spontaneous inflammation in the veins of the upper extremity, such condition is far from being uncommon in those of the lower. This observation applies particularly to the saphena major, or its branches, although it is by no means unusual to meet
with this affection in the superficial or common femoral veins. In most of these cases, the inflammation may be traced to some injury or over-exertion, but in some the cause cannot so readily be made out. The condition itself can rarely be mistaken,—the hard and painful cord in the site of the affected vein being a very palpable indication. This is especially observable in the saphena, but some careful manipulation may be needful to detect the thickened state of the deeper veins. If the common femoral be the seat of disease, and if the latter be severe, there is great edema of the whole limb, resulting from obstruction (temporary or permanent, as may be) of the great venous channel. Such a condition of the limb is common in inflammation of the great veins within the pelvis, and is probably more familiar to the accoucheur than to the ordinary surgeon, under the name of "white leg." Some have the idea that the "white leg" can occur only in the female, but I have seen as distinct cases of it in the male as in the other sex, and cannot see any reason why it may not be as common and as conspicuous in the one as in the other. The treatment needs no special notice here. Leeches, fomentations, calomel with opium, occasional laxatives, and the horizontal position, will be resorted to by one conversant with the principles of practice, and—conjoined with the use of a bandage, time must be permitted to elapse ere much can be made of the limb.

As with injuries, inflammation, whether following them, or of spontaneous origin, produces more inconvenience in general than a similar condition in the upper extremity. The necessity for the prone position can be more readily borne with persons in certain avocations than by others. Many of the common forms of ulcers have their seat on the leg, and the difficulty of treating such cases without the horizontal position is well known. If such a position can be maintained at the will and judgment of the surgeon, little else but attention to cleanliness, as regards the sore, is required, but as this confinement interferes so much both with occupation and the desire which most men have to move about, the efforts of the surgeon have been chiefly directed to such a mode of treatment as should permit of free movement in the upright position. This may be deemed the main features of the practice of Baynton and of Whateloy, and of all our modern authorities, among whom I may particularly mention Mr. Critchett—whose admirable lectures on the subject are well worthy of notice—and Mr. Startin, who has shown much skill and ingenuity in applying an elastic band of India-rubber in such cases, with the view of permitting the upright position. For additional information, I may also refer to the introductory section of this work, and to some future pages.

Mortification in its various forms is more frequently met with in the lower extremity than elsewhere, especially the cases resulting from disease of the heart, or blood-vessels, conjoined with old age.

Besides the derangements in the vascular system attendant upon inflammation, such as may be said to be common to all parts of the body, the vessels of the lower limbs seem peculiarly prone to disease. The veins are subject to permanent over-distension, such as is rarely
met with in other localities. A varix is seldom seen in any other part, and the permanently swollen condition constituting varicose veins is hardly ever seen but in these limbs, the lower part of the trunk—near the anus, or in the spermatic cord. I have seen a varix in the popliteal vein as large as a walnut, and so closely in contact with the artery that it might have been mistaken for aneurism, and I have seen a similar condition in a vein over the instep with the circumference of the swelling so well defined that it might have been mistaken for an encysted tumour, had it not been that under pressure the growth disappeared most readily and returned again as soon as the blood was permitted to refill the pouch.

The local effects of chronic changes in the arterial tissue are more conspicuously observed in the lower limb than elsewhere. Atheromatous and calcareous changes often lead to obstruction of the vessels altogether, at a period, too, when old age cannot be referred to. I have seen mortification in the foot from such a cause at fifty-one years of age.

Aneurisms in various forms are met with perhaps more frequently in the lower extremity than in all other external parts (so called) of the body. Although occasionally seen in one or other of the tibial arteries, such cases are rare, but in the popliteal, superficial femoral, and common femoral, they are of common occurrence. The various modes of treatment peculiar to such cases will be specially noticed in a subsequent chapter, and as the subject of Aneurism has been considered in a preceding section, no additional notice of it seems requisite here.

Dislocations and fractures are very common in this extremity. This cannot be wondered at when it is considered that, besides the usual casualties from without, the lower limbs have much strain upon them in supporting the weight of the body, with the additional impetus which is so frequently combined. Such subjects will be treated at considerable length in future chapters.

Diseases of joints resulting from injury, or from spontaneous causes, are frequent in this member. Perhaps the articulation at the junction of the great toe with its metatarsal bone, the ankle, the knee, and hip-joint, are most frequently affected, but any one may suffer, and in the foot it is by no means unusual to see disease of several joints at the same time. In some of these instances it may be a question whether the affection of joints or disease of bones is of the greatest importance.

It can scarcely be said, that diseases of joints here differ in their essential features from affections of joints in the upper extremity. The symptoms, actions, and results, with some slight modifications, may be considered similar. Perhaps disease of the hip-joint may offer some conspicuous points of difference, and it must always be held in mind that, owing to the strain upon the articulations in the lower extremity when disease is present, its effects as regards lameness are more conspicuously seen than in the upper limb. As a general characteristic it may be said, that affections of joints produce more
permanent mischief in the lower limb, for, even with the best results in formidable cases, any defect that may remain is more conspicuous than in the superior extremity. In the elbow-joint, however extensive the disease, there is never any remarkable separation of articular surfaces, whereas in the knee there may be such displacement of bones that much unseemly deformity may result. Again, in the shoulder there never is any displacement analogous to that which so frequently takes place in the hip in certain forms of morbus coxarius. Whatever may be the extent of disease in the shoulder-joint, the head of the humerus usually maintains its natural position, but in a corresponding affection in the hip-joint the head of the femur is occasionally displaced, and thereafter rests on the dorsum ili. That this happens there can be no doubt, but I am disposed to think that it is a less frequent occurrence than many imagine. From peculiar circumstances my attention has been much drawn to this subject, and I feel quite assured that many instances of so-called dislocation on the ilium, when there is shortening of the limb, bending of the knee, and other symptoms characteristic of dislocation on the back of the ilium resulting from injury, are in reality examples of distortion from changes in the shape of the articular surfaces and neck of the femur.

In diseases of joints in the lower extremity, the sufferer is, as in the cases of other ailments, obliged to rest the limb. He may move about, crumbling, on the other limb, with or without the aid of sticks or crutches; but he cannot rest upon the affected limb with impunity. Even if the disease is in such a condition as to permit walking, there is considerable risk from sudden movements or twists, and so if the joint be kept steady by splints there will be less risk of mischief than if not thus protected. The advantage of such views has been long appreciated as regards the ankle and knee-joints, but it may be said that it is only of late years that the value of the practice has been recognised as applicable to the hip. Most surgeons now, however, pay attention to this feature of practice, and by means of apparatus, such as a common long splint, similar to that often used for fractures of the neck of the thigh-bone, keep the articular surfaces from the slightest movement. Some interesting examples, showing the advantage of this mode of treatment, were published in the Lancet, for 29th November, 1851, by Mr. J. C. Foster, of the Surrey Dispensary. In certain instances of disease of the hip-joint, the surgeon may be baffled in keeping the limb in a satisfactory condition during the active stage of the disease, but if he watches for an opportunity he may possibly be enabled, by the judicious application of splints or other apparatus, so to straighten the limb, that whilst great and conspicuous deformity is done away, the member may be so disposed as to be of much use afterwards. I have seen many striking examples of this in my own practice, and some in the profession, who have devoted special attention to deformities and contractions, whether natural or the result of disease, have displayed both skill and ingenuity in restoring distorted parts to a more natural state. In regard to the hip, I may refer to an interesting treatise by Mr. W. C. Hugman, who
devoted much study to this subject. If awkward position or deformity be the result merely of thickening, stiffness, or fibrous ankylosis, very little will serve to effect improvement, but if from bony junction between articular surfaces, it is very doubtful if the surgeon can interfere with advantage, or even with propriety. The practice, which was more talked of thirty years ago than in the present day, of breaking up union at articular extremities resulting from disease, seems to have gained few followers in this country,—but some notice will be taken of this subject in future chapters, and I, therefore, need not dwell on it here.

Tumours of almost every description may be found in the lower extremity, but they require no comments here, as many are referred to in other chapters, and considering the nature of other parts of this volume, it does not seem requisite that I should dwell longer upon this sketch of the surgery of the lower extremity.

CHAPTER II.

DISLOCATIONS.

Dislocations of the lower extremity may now be taken into consideration. Such injuries are of rare occurrence in the toes or between the metatarsal bones, and, indeed, even in the tarsus, the only displacement that can be looked upon in this light is when the astragalus is thrown out of its natural position, an accident which, comparatively speaking, is but rarely met with. Separation of the articular surfaces from each other is by no means unusual; but in general the destruction of the soft parts, as also of the bones, is so great, that the injury should with propriety be looked upon as a contusion of a most serious character, which may endanger the safety of the foot, and possibly necessitate amputation.

The great toe and its metatarsal bone are liable to a kind of displacement of slow and gradual character, constituting the condition termed "Bunion." In some individuals the distal extremities of the metatarsal bones have a considerable tendency to separate from each other; and as more latitude of movement is permitted on the outer and inner margin of the foot than in the other bones, any inconvenience which may result therefrom is experienced in these situations. The distal extremity of the metatarsal bone of the little toe is occasionally somewhat prominent, but seldom causes much inconvenience; in the great toe, however, the spreading out of the foot causes the end of the metatarsal bone to appear so prominent, that this condition is often mistaken for an organized tumour on the inside of the articulation. The swelling is occasioned almost solely by the end of the metatarsal bone, whose projection inwards is rendered more conspicuous by displacement of the toe itself, which slopes off from the metatarsal bone.
towards the other toes, so as to make the distortion more prominent. The feet of the female opera-dancer are usually more or less distorted in this way; the displacement being, doubtless, occasioned by the frequent habit of poising the body on this member, thus producing a "fantastic toe" of very different description from that to which the phrase usually has reference. The skin over the projection is generally thinner than in the natural condition, the internal lateral ligament is more elongated, and in some instances the head of the bone is enlarged; it occasionally happens, however, more particularly during inflammation of the surface—a condition to which it is remarkably subject, in consequence of pressure,—that the soft parts actually seem to be thicker than in the natural state. The inflammation may be in the skin only; it may, however, extend to the joint, or in some instances its effects may be most conspicuous in a bursa, which is sometimes present in this situation. The disease is exceedingly troublesome, particularly if ulceration within the joint is present,—an event which is by no means unusual,—for then even the slightest pressure (which is at all times annoying) cannot be borne; but unless the joint becomes permanently affected, no active surgical means beyond those usually adopted in local inflammation are required; rest and the horizontal position will be of the utmost consequence if the latter disease be in a state of activity, and, under ordinary circumstances, a shoe made of soft leather or other material, and so constructed as to save the part from pressure, should always be worn; no further special instructions seem necessary here, and I will therefore only caution the young surgeon not to mistake such a swelling for a tumour of another kind, and resort to an operation for its removal, which will reflect great discredit on his professional character.

Drawing 191 exhibits an example of the kind of swelling referred to. The tumour in this case was slightly inflamed, but there was no ulceration present. There are few feet where such a projection is not more or less conspicuous, and that here exhibited is below the average size of what is so familiarly known under the title of bunion; it seems, therefore, sufficiently strange that the true nature of the disease should ever be mistaken; for in many instances the skin over the end of the metatarsal bone is actually so thin as to permit the outline of its shape to be most distinctly felt when the fingers are placed over the part.

The phalanges of the toes are liable to various forms of displacement and distortion, from the pressure of overtight shoes, for which no remedy but that of avoiding the cause will be of any avail; indeed, in most instances the cause is overlooked, and continued until its avoidance will not be of much benefit. One of the most annoying displace-
ments of this kind is that when the toe next the great one forms a sharp angle upwards, and the skin over it becomes affected with a corn, which is even more troublesome in this situation than on other parts. The projection is usually seen at the junction between the proximal and middle phalanges; it seems to occur most frequently in the originally well-formed foot, in which this toe is a little longer than the others; and though probably a short shoe is the chief cause of the displacement, I imagine that there is a natural tendency to it, from the slender shape of the part and the influence of the flexor and extensor muscles. The latter seem to draw the distal extremity of the first phalanx upwards and backwards, whilst the former apparently have most effect on the furthest end of the toe, and, by drawing it downwards, increase the displacement. It is seldom that the surgeon is consulted in cases of this kind; the operation of dividing the flexor tendons immediately under, has been proposed, and I believe the anticipated results might be greatly facilitated were the extensors also cut across above the root of the toe. By using a small knife, like that for tenotomy afterwards depicted, and taking care to avoid the joints, no danger can result from such operations. Some time ago I was consulted in a case of this kind, which the patient deemed congenital, his father's foot being affected in a similar manner. I divided the flexor tendons, with the knife referred to, immediately under the proximal phalanx, put a small piece of wood below the toe, and with some turns of a narrow slip of adhesive plaster kept it in its place and at the same time applied sufficient force to cause extension, when, in a few days, the part was as straight as that on the other foot, and the cure was complete. Sir Astley Cooper refers to a case of a similar kind. Within these few years I have frequently performed the above sort of operation with great advantage. In some instances, however, there has been considerable tendency to a return of the distortion, and in one this has actually happened, although the person does not suffer so much as before. The greatest trouble with the toe in this condition is commonly from the pressure against the upper-leather of the shoe; but I have seen the part so much bent under the foot, that the patient requested amputation of the offending member, which was accordingly performed. I have occasionally seen subcutaneous division of the extensors of great use in preventing the toes knuckling up, particularly in the little toe, which is the one most generally at fault, and in various instances have divided the whole extensors with excellent effect.

The astragalus is occasionally thrown out of its position, under the influence of a similar kind of force as that which would, in other instances, produce fracture of one or both bones of the leg, or displacement of the whole foot at the ankle-joint. Perhaps in general a greater power is required to detach this bone from its strong connexions with the os calcis, and force it from under the tibia and fibula, than would occasion any of the injuries alluded to; yet I have known it driven partially from its position by a degree of violence which was supposed to have caused merely a simple twist or sprain. The bone is
DISLOCATIONS OF THE ASTRAGALUS. 315

almost invariably thrown forwards, in front of the external malleolus; in some rare cases, the integuments are not wounded, but in general a portion of the bone projects, and sometimes it is, in a manner, completely detached from all its connexions. In the museum at King's College there is an astragalus preserved which was thus forced out of its situation, and the surface is completely divested of all fibres and ligaments, as if the dissector had carefully removed them with a knife.

From the manner in which the bone is protected by the malleoli, it is barely possible that displacement outwards or inwards can occur, and it is very unusual to see it backwards. Mr. Benjamin Philips has related two cases of the latter kind in the fourteenth volume of the Medical Gazette, and I have myself met with one instance. At first it was treated as a severe contusion of the ankle, and it was only after the swelling had partially subsided, and at a period when it was too late to make any attempt, with propriety, to replace the bone, that this feature in the case was discovered. An effort was subsequently made by a charlatan to put matters right by force, but it nearly cost the patient his foot. The bone projected so far back as to touch the tendo Achillis; yet although he was exceedingly lame for many months after the accident, I observed a gradual improvement, and have since heard that he has, in a great degree, recovered the use of the foot and ankle. There is a cast of this foot in my part of the collection at King's College: at a first glance it is difficult to perceive that anything is wrong; but, on a more careful inspection, the fulness of the ankle and tendo Achillis becomes apparent.

Dislocation of the astragalus, in any direction, and under any circumstances, must be looked upon as a very serious injury: for although many instances have been seen where life and limb have been preserved, even under great disadvantages, it must be admitted that such satisfactory results have not always followed the praiseworthy attempts of the surgeon to avoid amputation.

Under ordinary circumstances, and if the case is seen soon after the accident, an attempt should be made to replace the bone, by pushing it with the thumbs into its natural position, whilst extending force is applied by pulling the foot downwards in the long axis of the leg. Should the effort succeed, the treatment may afterwards be conducted as if the case had been one of severe sprain: leeches, rest, warm or cold applications, anodyne and stimulating liniments, with bandages towards the latter part of the treatment, may one and all be requisite, and probably the bandage with starch (to be afterwards more particularly alluded to) may be highly serviceable. It has been proposed in cases where the reduction is difficult, to divide some of the neighbouring tendons by subcutaneous sections, and possibly in certain instances there might appear some encouragement to do so: certainly the practice would, if judiciously applied, do no harm.

If the integuments are extensively wounded, and much stretched, as happens when the bone is thrown forwards, it may be a question whether an attempt be made to push it into its natural position or that it be entirely removed. I should be inclined, under such circum-
stances, to adopt the latter practice, particularly if the bone seemed (as would be most likely) but loosely connected to the neighbouring parts.

Some years ago I met with an instance of partial luxation of the foot forwards, which had not been noticed. Suppuration had occurred in the distorted ankle-joint, and a considerable opening had formed on the outer and fore-part of the joint, through which the osseous articular surface of the astragalus, from which the cartilage had disappeared, was plainly perceptible. A kind of ankylosis had occurred at the ankle when I first saw the patient, and perceiving after a time that there was no probability of the bare part of the astragalus exfoliating, I removed it with the most satisfactory result. A slight enlargement of the opening in the skin was sufficient to let me apply a small Hey's saw, in such a manner as to avoid injuring important parts in the vicinity.

I have met with an unreduced dislocation of the astragalus forwards; the accident had occurred many years previously, and the person, an active old soldier, had regained tolerable use of the foot and new ankle-joint, which was formed partly on the posterior portion of the displaced bone, and partly on the upper surface of the os calcis; he required the use of a stick, however, and walked on the fore-part of the sole of the foot, which was pointed downwards, like a person with talipes equinus, or one recovered after dislocation of the femur from hip disease, of which distortion there is a good illustration in p. 327.

Mr. Turner, of Manchester, has favoured the profession with an admirable essay on dislocation of the astragalus, which has been published in the Transactions of the Provincial Medical and Surgical Association (vol. xi.), and in which he has collected the particulars of nearly fifty cases of this kind. There is great encouragement from these instances to make every attempt to save the foot instead of resorting to amputation, even in examples where luxation is compound, and complicated, too, with fracture. Out of eighteen cases of complete excision of the displaced bone, fourteen made good recoveries, and in one of these only was there ankylosis. Were removal of this bone resorted to, or, indeed, in any case of dislocation of a severe character, the after-treatment would be much the same as for compound fracture in the lower part of the leg.

Dislocation of the foot at the ankle-joint is more frequently met with than the cases last alluded to; the foot may be thrown backwards or forwards, and in either example there can be no difficulty in perceiving its nature, by the increase or the diminution of the projection of the heel.

The first of these is represented in sketch 192, in which the distance between the tibia and the tocs is diminished, whilst the heel is more prominent than natural. The fibula is fractured above the malleolus, and it will rarely be otherwise. Figure 193 shows the displacement of the foot forwards, the tibia resting on the upper and back part of the os calcis, the fibula being broken in this instance also. In both of these drawings the attitude is such as would most probably be present, although it might vary in many respects, which, however, require no particular comment here.
Such displacements as those here delineated are comparatively rare,

and the same may be said of that of the foot inwards, the fibula and tibia being thrown to the outer side of the tarsus. In this case the malleolus internus will, in almost all instances, be broken; and in all probability the fibula will have suffered in the same way. Sketch 194 gives a diagram of such a case, although,

were the parts so much displaced as is here represented, there would doubtless be wounds in the integuments, through which some of the fragments would project.

The most common kind of dislocation at the ankle—viz., that wherein the foot is thrown outwards, whilst the bones of the leg glide inwards, is represented in fig. 195, in which, for the sake of distinctness, the distortion is made to appear more conspicuous, and the separation greater, perhaps, than might be in reality; here it will be observed that the fibula is broken higher up than in the preceding figures; such an injury invariably happens in cases of this description (indeed, it is not unusual to speak of the case more as one of fracture than of dislocation, however palpable the latter may be), and the
malleolus internus is almost certain to be separated from the tibia. In the drawing it is represented as being still attached to the bone, though there is a slight fissure, but in reality it would probably be retained in its natural position below by the deltoid ligament.

Some years ago I met with an instance of luxation at the ankle-joint, such as I had previously not known. The late Mr. Dickman, of Porchester Place, called me to see a young man, aged twenty-three, of athletic frame, who had met with a severe injury at the ankle during a scuffle with some of his companions. He had fallen at the time of the accident, and it was supposed that some one had trampled upon the injured part. The foot was twisted outwards, so that the toes were directly out from the malleolus externus. The accident being recent there was no perceptible effusion of blood or swelling, and the parts could be very readily examined and recognised. The malleolus internus could be felt distinctly under the skin, which was here on the stretch, and so also could be the anterior margin of the articular surface of the tibia. The outer malleolus was also distinct, but somewhat lower on the foot than natural, and the distance between it and the internal malleolus was remarkable. The astragalus could not be clearly made out, but it seemed as if jammed between the ends of the two long bones. On extension being made under chloroform, reduction was very easily effected, and during as also after the process, I satisfied myself that the principal feature of the injury was a luxation of the foot upwards, between the two bones of the leg. The ligaments which bind these bones together had given way and permitted the astragalus to slip between. There was no fracture that could be perceived. I am not aware that such an injury has heretofore been described. It might be called luxation of the foot upwards. A bandage was applied immediately after, and then a common side splint was put on. There did not appear the least tendency in the foot to slip upwards, and a very speedy recovery ensued. I have since seen a similar instance, caused by a horse falling on the street, with the rider's foot below, and think that luxation of this kind is worthy of notice. Figure 196 illustrates the subject, but for the sake of showing the astragalus distinctly the foot is not twisted as described above.

The common principles of surgery will indicate the necessary proceedings in all these dislocations at the ankle. Gradual extension, with the limb bent at the knee and the foot at a right angle with the leg, and gentle movements at the joint, will effect reduction. Ordinary precaution to avert or subdue high inflammation being carefully attended to, the parts will, after due time, in great measure recover their original
power of resisting the varied and complicated influences under which the ankle-joint is exposed to injuries of the most serious description; but I shall not dwell longer upon these cases at present, as it will be necessary again to allude to them in the chapter on fractures, to which I must refer the reader for further information.

Even in most instances of compound dislocation this fortunate result may be looked for, although in occasional examples the destruction of parts is such, and other circumstances are so unfavourable, that amputation will be the safest measure for the patient.

The evidence collected by Sir Astley Cooper seems to settle the line of practice to be followed in by far the greater number of injuries of the ankle-joint; whether the case be one of simple or of compound dislocation, or the latter, complicated with extensive wound of the skin, contusion, and laceration of the other soft parts, and even severe fracture of the bones in the vicinity, the surgeon is fully entitled to give the patient a chance of having his foot preserved. Chloroform may be used and the pulleys may be applied to facilitate reduction, where much difficulty is experienced; loose portions of bone must be picked away; projections may be cut off with the saw or pliers, or the aperture in the skin enlarged with the knife; in short, any reasonable expedient may be resorted to in order to save the foot, which, whatever be its after condition, will in general be preferred, by most patients, to any artificial substitute.

In the example here represented (fig. 197), it was deemed expedient to remove the foot, in consequence of the apparent extent of injury to the soft parts in front of the joint; but the practice seems very questionable, when, in the evidence above referred to, it is proved, in some of the cases, that the patients actually stood and walked on the protruded end of the tibia, and yet most satisfactory recoveries followed. Primary amputation in this instance was performed, but did not succeed. Whether the patient would have had a better chance for life with his foot on, or by waiting till the period for secondary amputation, it is impossible to say, but it appears that under any circumstances amputation in cases of the kind is far from being successful. It has been stated by Mr. Syme (Edinburgh Monthly Medical Journal, August, 1844), that out of thirteen operations of the kind performed in the Royal Infirmary of Edinburgh, only two of the patients recovered,—an amount of mortality which may well incline the surgeon to act upon the doctrines inculcated by Sir Astley Cooper. I fear, however, that in the attempts which have been made to save the foot, the results in all the cases have not met with the same pub-
licity; that the instances where amputation has afterwards been necessary, or where death has been the consequence, have not also been recorded; and from what I have myself seen, I would caution the inexperienced practitioner from being over sanguine in anticipating a happy result in every example. Mr. Pott, in referring to fracture of the fibula, with displacement of the foot outwards, and protrusions of the end of the tibia inwards, stated that "when this accident is accompanied, as it sometimes is, with a wound of the integuments of the inner ankle, and that made by the protrusion of the bone, it not un­fre­quent­ly ends in a fatal gangrene, unless prevented by timely amputation, though," he adds, "I have several times seen it do very well without."

Drawing 198 represents the condition in an instance where I advised and performed amputation. The case occurred in the practice of my friend, the late Mr. Sedgwick, of Maidstone, who had made a most laudable attempt to save the foot. Severe inflammation and suppuration followed the injury, and although there was accurate adjustment at first, the displacement shown in the figure gradually occurred: the end of the tibia became partially exposed and necrosed; the articular surfaces of the ankle-joint had been eroded, and these circumstances, conjoined with the exhausted state of the patient's constitution, rendered an operation imperatively necessary. It was accordingly done about the middle of the leg, and the patient made a good, although a very protracted recovery. Doubtless amputation at the ankle by Syme's or Pirogoff's plan would now be preferred to amputation in the leg, and figure 197 would have admitted of either, for the rent in front is just in the line of one of the incisions, as may be seen by reference to the drawing some pages further on, which illustrates amputation at this articulation.

In severe injuries of the ankle, the fibula has been separated from the tibia, but the accompanying fractures and dislocations have always formed the most conspicuous and serious features of each case. Most likely in the accident depicted in figure 196 the interosseous ligament was rent, or greatly overstretched, throughout its whole extent. The upper extremity of the fibula has occasionally been separated from the tibia, but the accident is rare, and being at the same time in all likelihood accompanied with fracture of the tibia lower down, no separate comment upon it is here required.

The bones of the knee-joint may be displaced in almost any direction. The patella will be drawn upwards, in the event of the accidental
division or rupture of its ligament; and when the tibia and femur are thrown out of their natural position, this bone must also be more or less displaced. In some individuals, a very trifling force will cause the patella to slip in front of either condyle of the femur, particularly when the limb is in a horizontal position, with the muscles on the fore-part of the thigh in a relaxed state; I have known displacement occasioned, under these circumstances, by a child resting its foot on a person’s knee, in stepping across to get out of bed. Drawings 199 and 200 exhibit the lateral displacements referred to; and unless there be great swelling, the nature of either case must be easily detected, in consequence of the prominence of the bone; nor is there much difficulty to be looked for in replacing it,—an operation which is accomplished chiefly by the thumbs, with which the surgeon forces the bone over the margin of the articular cartilage into its natural position.

The necessary manipulations will be greatly facilitated by bending the body forwards, which will relax the rectus femoris muscle.

It has been found in instances where these simple means have failed, that violent flexion of the knee has brought the patella into its natural position. In a case of extreme obstinacy, the ligamentum patellae has been divided, but the operation did not seem to favour the desired result; however, a good anatomist, in any similar example, might resort advantageously to some subcutaneous section.

The head of the tibia is occasionally driven off the condyles of the femur in a lateral direction, but seldom to any great extent, and dislocation between these bones is generally either backwards or forwards. Figures 201 and 202 exhibit the partial displacements laterally, and 203 and 204 display the luxations backwards and forwards. It is hardly possible to state which is the more severe injury, both being certainly of the most serious description; perhaps that with the tibia forwards is the worst, as, in addition to the extensive laceration of ligaments and other textures which happens in either instance, the projection of the lower part of the femur backwards may overstretch and lacerate the popliteal artery. I have seen this happen in one instance, but in that case the displacement was such that the condyles
of the femur were forced through the skin of the ham. Dr. Houston, of Dublin, related (Dublin Hospital Reports, February 15th, 1845) an instance of this sort wherein a kind of dry gangrene was the result, which he attributed to injury of this artery. The large bones have alone been displayed, as, if the patella had been left, or any of the soft parts, the student might have had some difficulty in appreciating the nature of each. The limbs are here represented in almost straight positions, but in such extensive injuries it will not be difficult to understand that the knee may be greatly bent, as is conspicuous in one of the casts at King's College.

In reducing luxations of the head of the tibia, the extending force, whether by means of the hands or pulleys, should be applied to the upper part of the leg, and it may be advantageous to fix the counter-extension on the pelvis, so as to avoid pressure on the muscles of the thigh, which might thereby be prevented from being relaxed or elongated, or might even be irritated into contraction. The difficulty in effecting the object of the operation will not in general be very great; and, provided there has been no serious injury of the soft parts, or, in other words, no extensive displacement, a recovery may reasonably be anticipated. The utmost care, however, will be required to avert injurious inflammation, which may, nevertheless, supervene and terminate, as I have seen, in the loss of the limb, or
death of the patient. Indeed, considering the extent of injury, even in what is called a simple dislocation, and the dangerous nature of inflammation on this joint,—a process which must inevitably result from the accident, the question of immediate amputation may be very seriously entertained; and in most examples of compound dislocation, I think there can be little doubt that the safety of the patient is endangered by delay: the alternative is dreadful; but, in my opinion, amputation is the least formidable of the two. Even in some instances of compound luxation of the knee, it may be reasonable to attempt to save the limb; and in partial displacements with no external injuries, a judicious surgeon would not for an instant entertain the idea of mutilating the body, until, in the progress of the case, circumstances should arise to compel him to adopt this last resource. Some years ago, I was consulted in a case of partial dislocation of this joint, which had occurred simultaneously with a fracture in the lower end of the femur. At first the injury was treated merely as fracture; in about six weeks, when the splints were removed, and the swelling had greatly subsided, the knee was observed to be remarkably stiff; and, for the first time, the inner margin of the head of the tibia was felt to project half an inch within the level of the corresponding condyle of the femur. Figure 202 shows such a displacement, although here the tibia projects a little more than in the case alluded to. I deemed it too late to attempt the reposition of the bones, but noticed in the course of time that the patient regained a fair use of the joint. I have lately seen another instance of this kind in a patient in King's College Hospital. The injury was of old date, and although the tibia projected inwards very conspicuously, the joint seemed little the worse in regard to its movements.

In some examples suspicions have been entertained, that pain and difficulty in moving the knee, accompanied with the feeling of something being between the bones, have been occasioned by displacement of one of the semilunar cartilages. Such cases have been described by Mr. Hey, Sir A. Cooper, and others; I have myself seen many supposed to be of the kind, and have observed an instance in the dissecting-room, where one of these cartilages had been torn from its connexion with the tibia, throughout its whole length, with the exception of its extremities, so that during flexion and extension, it must have occasionally slipped behind the articular surfaces; and this happening during life, as undoubtedly it did, must at the very least, have caused considerable annoyance. The cartilage was flattened on its outer margin, and, when it passed behind the condyle of the femur, seemed to fit to the articular surfaces almost as accurately as the internal concavity does in the natural position of the parts. Such displacement might possibly occur in some slight injury or awkward movement of the joint (indeed, the supposed cases which have been seen in the living body have usually been caused in some such way), or it might happen with dislocation of the tibia. Were the surgeon to detect its nature, the most reasonable treatment would consist in first endeavouring to cause the cartilages to slip forwards, by flexing and extending the
joint, and, this being accomplished, restraining for a considerable
time further extensivc motion, by means of a bandage or leather
cap, so as to give the movable object a chance of becoming again
fixed in its proper position. The caoutchouc roller, or an appa-
ratus of the same material, made to give support to the knee, at
the same time permitting slight flexion, might be very useful in
such cases.

Within the last few years I have seen several examples of so marked
a kind, that I could not doubt that some such displacement as above
described had occurred. One of them I have seen very recently. A
gentleman, about forty years of age, sent for me under these circum-
stances:—About twenty years before he had sprained his knee, and,
besides suffering considerable pain in it, had been unable to stretch
the limb fully, or, indeed, make any use of the lower extremity. After
many things had been tried with no good effect, a sudden slip was
noticed during an accidental movement of the leg, and immediately
thereafter the patient was conscious that he could move his knee freely
and without pain. Soon after a slip like the first took place again,
when, by moving the leg, another slip was caused, which gave imme-
diate relief. Such occurrences became so frequent,—often happening
in bed, that the sufferer soon acquired a tolerably accurate mode of
dealing with them. The mischief was always on the outer side of the
right knee, just between the articular surfaces of the external condyle
of the femur and corresponding part of the tibia. The limb during
the displacement could never be fully straightened, until, by pointing
the toes outward as much as possible, and then lifting the foot forward,
—which the patient usually did with the other foot behind the tendo
Achillis, a sudden slip at the knee was felt, when all was at once right
again! A bandage or knee-cap was generally worn during the day,
but at night it was laid aside, and then a slight movement in bed was
apt to produce the mischief. When I saw the case there had been
lameness for about a fortnight, and fear was entertained that matters
would not right themselves, as on former occasions. I tried a variety
of movements of the joint, but with no good effect, and I did not think
it advisable, under the circumstances, to use much force. Two days
afterwards a sudden slip took place, and the parts went all right again.
I have seen two other instances within the last twelve months, where
there was every reason to suspect such displacement of a semilunar
cartilage, and in both of them there appears every likelihood of per-
manent lameness. Further experience confirms in my mind the general
tenor of these observations. In one instance flexion of the joint will
seem to display the perfection of manipulation, but in others the most
free and skilled-looking movements will be of no avail.

Notwithstanding the vast natural strength of the hip-joint, as evinced
in the shape of the bones, their adaptation and ligamentous connexions
to each other, as also the great power of the surrounding muscles, dislo-
cations are by no means uncommon in this articulation. The head of the
femur may be thrown upwards on the dorsum illi, or it may pass back-
wards, and rest on the margin of, or actually in, the sacro-sciatic notch;
in other instances it may pass forwards and inwards so as to rest on the body of the pubes; and in some cases it passes forwards and downwards into the obturator foramen. The precise spot on which the head of the bone rests is seldom the same in any two cases: upwards, for example, it has been found to range, in different instances, throughout every point between the anterior spinous processes and the sacro-sciatic notch, and in the other directions, considerable differences in position have been remarked; in one example, the limb will appear much shorter, compared with its fellow, than in another: again, the toes or foot may be more pointed inwards or outwards in one patient than in another, and all these circumstances, it will be perceived, indicate corresponding varieties in the position of the head of the bone.

Figure 205 exhibits the skeleton of the displacement upwards and backwards; the shaft of the bone (at the trochanter) would probably lie more completely over the acetabulum. Here the head may be in some cases a little nearer the anterior part of the crest,—perhaps immediately under the anterior spine,—possibly a little more forwards, or it may be further backwards, and either more downwards or upwards; of which, however, though examples of all such cases have been seen, I do not think it necessary to give pictorial illustrations.

Drawing 206 shows a rarer kind of displacement: here the head of the bone is hooked, as it were upon the horizontal ramus of the pubes, having passed partly into the pelvis; but in luxation in this situation, too, there may be some little variety, and in all probability the head will not in general be driven so deep.
In design 207 the head of the femur is lodged in the obturator foramen; and here, perhaps, there is less difference in position observed than in the preceding examples: it may, however, not be so close on the pubes as represented, but occupy the opening more completely than it does in the drawing.

Some of these dislocations will be further illustrated in the succeeding pages.

In general there is little difficulty in detecting the nature of such injuries; nevertheless, either through ignorance or neglect, they are occasionally overlooked until it is too late to remedy the misfortune. Most surgeons must have seen deplorable cases of the kind, and I have met with many. In one instance the accident (a dislocation on the dorsum illii of a very palpable kind) was complicated with fracture in the lower third of the femur; the case was treated as one of fracture, and the dislocation was not detected for some considerable time. After the fragments had united, several attempts were made to replace the head of the bone, but to no purpose, and the shortening of the limb, between the dislocation and fracture together, was such as to render the patient very miserable, and unfit for all active pedestrianism. It may be doubted whether in this example the dislocation could have been reduced at the first, in consequence of the injury in the lower part of the thigh; yet it would have been creditable to surgery had its nature not been overlooked, and some reasonable attempt been made to remedy the aggravated evil.

In the dislocation upwards on the dorsum illii (fig. 205) the head of the femur is thrust under, into, or it may be through, the substance of the gluteus minimus muscle, and rests about one inch and a half or two inches above the margin of the acetabular cavity; the distance being in one example greater, in another less. Figure 208 gives a correct representation in outline of the distortion of the limb, which appears shortened and bent at the joints, with the thigh sloping towards its fellow—the knee touching its lower third, and the great toe in contact with the metatarsal bone of that of the opposite side. The shortening of the limb will vary according to the position of the head of the femur, and although it is very characteristic of the accident, particularly when concomitant with the attitude here delineated, it should not always be relied on as a positive indication of this kind of displacement. The hip itself should be most carefully examined: if the injury be such as that under consideration, it will readily be perceived that the trochanter major is nearer to the crest and anterior and superior spine of the ilium than the same process is on the opposite side; and possibly
the head of the bone may be felt in its new position: it will be observed, also, that all movements of the thigh on the pelvis are attended with pain, and accomplished with difficulty, and that a slight degree of force will neither suffice to extend the limb to the length of its fellow, nor alter the apparent distortion of the hip. The contrast between this injury and that of fracture in the neck of the femur may be fully appreciated by a reference to one of the drawings illustrative of the latter subject, which will be seen on page 358. Mistakes occasionally occur in the diagnosis between these accidents; but, however discreditable and injurious they may be, the ignorance or oversight is less reprehensible than that which leads to the treatment of a disease of the hip-joint, as if the case were one of dislocation. Many instances of this description have come to my knowledge, and although they have

in general occurred in the practice of the bone-setting charlatan, it is with regret that I cannot exculpate every member of the profession. I have known the mistake committed in the early stages of hip-disease, where there is scarcely a trace of resemblance between the cases; and if it takes place under such circumstances, it must be allowed that it is much more likely to happen at that period of the disease when luxation has actually occurred: indeed, so far as the shortening and attitude of the limb are concerned, and also the alteration in the shape of the hip itself, there is a great similarity: yet the points of difference are so glaring that it is barely possible to imagine a surgeon being so much at fault. The distortion resulting from disease is not usually so much referred to as that occurring from violence: drawing 209, from a cast in our collection at King's College, gives a
good example of the kind, and although the subject of morbus coxa-rius does not come within the scope of this section of the volume, I conceive my present observations by no means irrelevant. Before the age of puberty, dislocation of the hip-joint from violence is an exceedingly rare occurrence, and hip-disease leading to displacement is equally rare after this period of life; even the affection itself is comparatively unusual after this age. But a knowledge of such matters should not induce the surgeon to form a hasty conclusion, as cases illustrative of the converse are sometimes met with.

Years ago I had under treatment the most palpable case of spontaneous luxation in hip-disease which has ever come under my notice. A remarkably muscular man, about twenty-five years of age, had a large deep-seated abscess in the hip, which there was reason to suppose was connected, by an opening in the sacro-sciatic notch, with inflammation in the iliac fossa. In the course of three months, during which time he was confined to bed, several openings were formed in the loins to permit the escape of matter, and, latterly, the skin between the lumbar region and upper and back part of the thigh seemed one bag of fluid. For three weeks previous to death, he had suffered greatly from pain in the region of the hip, and would not allow the part to be touched;—indeed, he was so much exhausted that there was no inducement to make any attempt to examine the condition of the joint: during the latter period he lay with the thigh more bent upon the pelvis than ever, and the knee rested on the sound thigh fully four inches above the condyles of the femur: the trochanter appeared much nearer the anterior part of the crest of the ilium than previously, and a fullness on the dorsum illi became remarkably distinct before his death. On examining the body afterwards, these latter features were all most conspicuous; and when the skin was elevated, the head of the femur was found in the situation represented in figure 205: the round ligament was softened and torn across; the capsular—or rather what remained of it—and also the gluteus medius and minimus, with the smaller rotator muscles, were soft, pulpy, broken up, and so infiltrated with pus, that they could scarcely be recognised; and the head of the bone, saving that the cartilage was absorbed, was otherwise as entire as if the displacement had resulted from accidental force. The cotyloid ligament had disappeared, but the margin of the cavity where the head had slipped upwards, although in a state of caries, was as prominent as in the healthy condition. It is usually considered that the bones undergo considerable changes ere dislocation occurs in such instances, and I believe that they generally do: most preparations in museums, and experience in excisions on the living body, prove the latter fact, but I imagine that such examples as that just detailed are somewhat rare. I have often, in subsequent years, thought that excision of the head of the femur, since come into favour, might have given this patient a better chance of life.

There are peculiar features in the history of each case, which ought at once to lead to a correct estimation of its true nature; thus, in hip-disease, the patient will have been bedridden for months, perhaps for
DISLOCATIONS OF THE HIP-JOINT.

years, a sufferer from severe pain, which will have rather increased than otherwise from the commencement to the period of examination; the illness will have come on without any apparent cause; for although it may by the friends be attributed to a fall or some other accident, the surgeon will feel certain that immediate displacement could not have been produced thereby; on the other hand, in dislocations resulting directly from force, the person will have been exposed to some great violence, which has caused immediate lameness, and all the other symptoms of dislocation: if he has been neglected at this period, his sufferings, after the first few days, will have gradually diminished; and although the distortion will still remain as apparent as at first (perhaps even more so, as the extremity becomes thinner, which it will eventually do), he will, in some measure, have acquired a slight use of the member,—at all events, he will not suffer as a patient with hip-disease does when the limb is moved, nor will there be emaciation, suppuration, sinuses, and other marks of long-continued irritation, so characteristic of diseased joint: but I shall pursue this subject no further at present; and were it not that I had repeatedly seen instances where the wretched victims of hip-disease had been subjected to all the horrors and violence of attempts to return the femur to its proper position,—as is done with propriety in common luxation from force, I would not have dwelt so long on a subject with which every tyro should be conversant.

A singular case of oversight of this kind of injury once came under my notice. A young woman, about her full time of pregnancy, had a severe fall, and was carried to bed in a helpless condition: labour came on immediately after, and she had a difficult time. A severe rheumatic fever, as it was supposed, supervened, and for weeks her life was despaired of. I was asked to see her when comparatively well, about three months after the injury, and then for the first time a dislocation of the hip was detected. No doubt this injury had been sustained at the time she fell before labour came on, but by a train of circumstances, it had been overlooked. I now made an attempt to get the head of the bone from the margin of the great sacro-sciatic notch where it was, but without success. In the course of twelve months this young woman, although still very lame from the shortening of the limb and other circumstances, walked wonderfully well and was free from pain.

Reduction of dislocation on the back of the ilium is seldom attended with great difficulty. In general powerful force is required, and chloroform should be used to relax the muscular action. Here, as in regard to the shoulder-joint, the former practice with warm bath, tartarized antimony, bleeding, &c., is entirely obsolete. If the pulleys are at hand they ought always to be applied; for although manual efforts alone may suffice in some instances, the whole proceedings will be more satisfactorily conducted under the steady force which can be brought into play by such a powerful apparatus. The patient, as represented in figure 210, should be laid on his uninjured side, on a hair mattress placed on the floor; a broad linen or cotton cloth, folded
lengthwise, should be passed under the perineum, and its two ends should be fastened to some firm object in the floor or wall below the level of the patient's body. To prevent galling, a folded towel should be put between the cloth and the perineum. Another cloth, similar to the above, should now be fixed by its middle to the lower part of the

Fig. 210.

thigh (and here, also, to prevent mischief to the skin, a few turns of a roller should be previously made round the limb), and its ends should be joined by a firm knot. Instead of a linen cloth for the thigh, an apparatus of iron and leather (the zonula of Hildanus) has been constructed for the purpose of giving attachment to the pulley; but I recommend, in preference to either, the skein of worsted referred to at p. 220. When this is properly fastened by the clove-hitch (p. 210) to the thigh, a little above the knee, the hook of one pulley should be attached to it, and that of the other to some holdfast in the wall, directly opposite to the fixed extremity of the cloth under the perineum, in a line parallel with the long axis of the thigh, which will consequently cross obliquely that of the body, as seen in the drawing. I have recommended that the stay under the perineum should, at its extreme point, be fastened below the level of the hip, and that the end of the pulley most distant from the body should be fixed somewhat higher, in order that extension may be applied without disturbing the oblique line into which the femur has been thrown by the injury. The manner of fixing the two extremities of the whole apparatus is of more importance than some may imagine: thus, if that connected with the thigh is too low, when the extension is applied, the pelvis is forced towards the floor; and on the other hand, if too high, it is actually raised from the mattress, so as to form, as it were, part of the cord between the two fixed points. Nothing can be more unpleasant than to perceive the body swinging to and fro during the efforts of the surgeon. I prefer having the patient near the floor, but the same proceedings may be conducted on a firm table, in which case the fixed points must be high in proportion. In private practice it may be difficult to procure fixed points in an apartment, and I therefore beg attention to my remarks on this subject in the Chapter on Dislocations of the Shoulder; indeed, so requisite do I consider these points d'appui, that the pulleys should not be considered complete without some such contrivance as the staple or screw, of either of which a couple should be as regular an accompaniment of the pulleys as is the cord.
In the out-patient room or theatre of a hospital the case is different; a variety of rings, placed in walls or pillars at different heights and at different sides, are essential appendages.

The apparatus for extension and counter-extension being adjusted, the surgeon, desiring his assistant to commence extension, places himself at the patient's pelvis, and with his eyes and hands, ascertains the progress of the attempt. As the assistant continues to pull, the trochanter major, or perhaps the head of the bone, can be perceived gliding gradually downwards, and the descent will be greatly facilitated by moving the thigh in a rotatory manner on its long axis, which can be readily accomplished by laying hold of the leg at the ankle, and carrying the foot upwards and downwards. In most examples that have come under my notice, the extending force alone has been sufficient; but in some I have seen advantage derived from passing a long towel under the upper part of the thigh, with which the surgeon has endeavoured to raise the head of the femur over the margin of the cotyloid cavity, by pulling in a transverse direction to the force already in use, at the same time placing his foot on the pelvis by way of counter-extension. I believe that this method, in some instances, facilitates reduction, but feel satisfied that continued extension at the same time is necessary; and I have less faith in sudden and eccentric movements producing benefit in this dislocation than in most others. The snap, jerk, or shock which, when the reduction is accomplished, usually is observed by both patient and surgeon, sufficiently indicates the success of the effort; and if, when the apparatus is slackened, the movements at the joint can be easily effected,—the distortion has disappeared,—and the opposite sides are symmetrical, there need be no further doubt; the patient should then be carried to bed, and, with the legs tied together, kept quiet, until the soft parts are supposed to have united and regained proper strength.

In some instances, where the displacement has existed several weeks, I have known it necessary to repeat the attempts at reduction, the first having completely failed; and I have in some observed the most happy results. A surgeon, therefore, when he can reasonably hope to benefit his patient, should not at once give up a case as hopeless merely because he fails in the first trial: circumstances may be more favourable on a second attempt a few days afterwards; indeed, I may say a few minutes in some cases, as I have known an effort succeed with the hands alone within the lapse of a short space of time after the pulleys had been used to no purpose. The muscles in some individuals will make greater resistance to extension than in others, and the patient seemingly either cannot or will not relax them; in almost all, however, long continued or repeated extension will at last prove superior; and in some persons, after the pulleys have been used for a considerable time, and when perhaps the rope has been relaxed in despair, a kind of collapse will supervene, when the muscles will become so flaccid, that a very slight degree of force, compared with that previously applied, will produce the desired effect.
Possibly in examples of this kind of luxation, the adjuncts to the pulleys recommended by Mr. L'Estrange, or the apparatus of Dr. Jarvis, both of which are alluded to in the Chapter on Luxations of the Upper Extremity, might be found of advantage.

In the Dublin Medical Press, 3rd December, 1851, Dr. Mayr refers to "an easy mode of reducing a dislocated femur," as practised by himself, Dr. Fischcr of Cologne, and by Mr. Clarke of Southampton. This method consists in abducting the femur from the mesial line instead of pulling chiefly downwards. Success has followed this plan, when the ordinary process with pulleys had failed.

The dislocation of the head of the femur into the sciatic notch differs in no material practical point from that last referred to: it is caused by much the same kind of violence; the attitude and appearance of the limb are in many respects similar, the chief difference being, that the shortening is not so great, although the limb is shorter than its fellow by half an inch or more; that the trochanter and head, especially the latter, are not so distinguishable, or, if they are, they will be perceived to be a little further backwards and downwards than in the other instance; and that in the effort at reduction, the transverse force is particularly requisite from the commencement, to facilitate the escape of the head of the bone from the notch, as also to assist in raising it over the margin of the acetabulum. I need scarcely point out to my readers that much violence is often necessary in these attempts, and think it would be incorrect to conceal the fact; for, however easily reduction may be accomplished in some instances, it must have been observed by all who have had much experience in such practice, that, in the majority of cases, big drops of moisture have stood on the brow of every one actively concerned, before success has been attained.

When the head of the femur rests on the pubes (p. 325), the whole limb is everted, the knee is slightly bent, the trochanter is less prominent than natural, and the displaced part can be distinctly felt in the groin under Poupart's ligament. One would imagine that a displacement of this kind could scarcely be overlooked, yet specimens of false joints formed in such cases are to be found in most museums, and afford convincing proof, either that such injuries are neglected by the patients, or overlooked by the surgeon.

The apparatus and extending force applied as described for dislocation upwards and backwards will produce the desired effect in this instance also; and the transverse force as recommended to assist in raising the head of the femur from the sciatic notch, will here be of equal service; for, as the patient lies on his side, the thigh-bone requires to be lifted upwards, perhaps even a little forwards, as may be imagined from an examination of the cut referred to, into its natural position, and indeed, perhaps, this force is more essential than extension. In such a case Dr. Mayr recommends adduction of the thigh.

The displacement into the thyroid foramen (p. 326) is probably the most rare that occurs at this articulation; like the rest, it too seems to be overlooked in some cases.
DISLOCATIONS OF THE HIP-JOINT.

The attitude somewhat resembles that of the kind last referred to; but the limb is more bent on the pelvis, considerably elongated, and as it were, thrown downwards and forwards. Flatness of the hip, sinking of the trochanter, swelling in the upper and inner part of the thigh, occasioned by the head of the bone in its new situation, and the natural condition of the pubes, contrasted with the dislocation last-described, will sufficiently indicate the true nature of the case. Extension can scarcely be deemed requisite in affecting reduction in this case: I am inclined, however, to recommend a slight degree of it, as the patient's body can thus be kept more steady. Transverse force must then be applied in the manner above-described, and in all likelihood the parts will speedily be adjusted; far less energy being required in this case than in any of the others. If the head of the bone cannot be raised by the single efforts of the surgeon, he may either employ additional hands, or, what will be better, apply the pulleys in the manner represented in figure 211.

The strap on one side serves to fix the pelvis, whilst that on the other, when the pulleys are in action, answers the double purpose of raising the head of the bone and of a fulcrum, on which, by carrying the limb towards its fellow, the femur is moved as a lever, whereby the desired object is facilitated. Occasionally, instead of keeping the patient's limb in an extended posture, it may be better to bend the thigh upon the trunk, or to make him sit upright, as was advised by White, Kirkland, and Hey, with the body so placed against a bed-post or upright pillar, as to constitute a fixed point or fulcrum in the perineum, around which the displaced bone may be so turned as to cause its head to slip backwards into its natural position. I have seen an upright pin, like the remora of Hildanus, or the scalmus on the scapnum of Hippocrates, nine inches long, placed in a stout table intended to be used for such purposes, and at the London Hospital, where these injuries are more frequently met with than at most other similar establishments in the metropolis, it is customary to fix a pillar of wood into the floor (a hole being provided for its reception), which is used in the manner above referred to.

These observations are intended to convey an outline only of dislocations of the hip, and the methods of reduction; but as the nature of this work will not permit me to dwell at greater length on the subject,
it is to be hoped that, combined with a knowledge of anatomy, which will point out the kind of resistance to be overcome, and a moderate share of mechanical knowledge, which will indicate the natural direction of the force required to cause the head of the femur to retrace its course, little difficulty will be experienced in making up such deficiencies as must be the necessary result of these brief descriptions.

For the hip there have been fewer different methods described than for the shoulder; and this may, probably, be accounted for by the fact, that until towards the end of last century, little accurate knowledge obtained of such cases. Wiseman wholly denied and disbelieved in such luxations; Boerhaave, nearly a century later, supposed that there could be no such thing; and although Heister quotes Hippocrates and Zwinger on the subject, and describes the method of reducing the different kinds—"upward, downward, backward, and forward," he evidently had no clear ideas between the displacement in hip-disease, and that resulting from violence. A luxation on the dorsum ili is very clearly described by Charles White, of Manchester, which occurred to him in 1759, and which he readily reduced by means of "three or four" assistants pulling at the injured limb while the perineum was placed against an upright post; but assuredly we owe a deep debt of gratitude to Sir Astley Cooper for his labours on this most interesting department of surgery. I cannot quit this subject, without calling attention to my remarks on the various means of reducing luxations of the head of the humerus. I would not have the practitioner invariably to persist in one mode for each kind of displacement; he ought here also to be guided by that common sense, which is so essential a feature in the practice of good surgery.

Although I have strongly recommended the pulleys in such cases, I do not deem them absolutely necessary in all; indeed, as already stated, I have known the hands of the surgeon alone succeed, when other and more violent means had failed; I am therefore not surprised at the proposal of M. Colombot, and others of more modern date, to reduce such luxations by the hands only, although I take leave to express my doubt as to the superiority of the practice. This gentleman placed the body and limb in a favourable position for relaxing as much as possible, all the muscles likely to prevent the return of the head of the bone, and then by using the femur as a lever, and moving the limb in all directions, the reduction, during some fortunate chance, was accomplished. A similar method is known to have succeeded in the shoulder; and it has been affirmed, too, that an accidental twist of the thigh, received by a person falling over the gunwale of a boat, has caused the head of the bone to pass into its natural position, after dislocation had existed for more than a year. Possibly such an event has occurred by a forcible abduction of the limb, such as that alluded to in a preceding page, as practised by Fischer of Cologne, and others.

With reference to the most distant date at which it will be proper to attempt these operations, I shall here also call attention to my remarks on this subject in regard to the shoulder. I have seen attempts made in various instances of old standing, but have not witnessed a
successful effort beyond the period of three weeks. Sir Astley Cooper has described instances of a more fortunate kind, after the lapse of four, five, six, and seven weeks; and I should certainly deem it quite correct to make trial of all reasonable means, at a much longer date than this, although, after two or three months, I should not be at all sanguine of a favourable result.

I purposely omit any particular allusions to congenital luxations of the hip, as not coming strictly within the scope of this work.

CHAPTER III.

FRACTURES.

FRACTURES of the lower extremity are, generally, more serious in their nature than those of the upper, being accompanied with more danger to limb and life, and much more trouble in their treatment.

In the foot such injuries are comparatively of rare occurrence; and when they do happen, the destruction of the soft parts is usually so extensive, that each case must be considered more as a contused and lacerated wound of all the textures around, than as a fracture, whether simple or compound. One or more of the toes may be thus injured by heavy weights, as may be noticed in coalheavers, quarry-men, stonemasons, and others similarly exposed; and as amputation is the advisable resource in most of such cases, the question of greatest importance for consideration will be with reference to the seat of operation. Unless the tarsus be involved in the injury, the idea of amputating the foot ought not to be entertained; and as a general rule, applicable here as in most other parts of the body, the smallest possible degree of mutilation ought to be inflicted, consistent with the object of the operation, which is to remove such parts as are irrecoverably injured, and, at the same time, leave a properly-formed stump. In instances of fracture in the foot where there is no necessity for resorting to the knife, it is scarcely requisite to use any apparatus to keep the fragments in apposition; in the toes the phalanges are so short, that if properly adjusted at first, they will remain so, unless the patient injudiciously bears his weight on the foot at too early a period; even in the longer metatarsal bones I have not found it necessary to apply splints; leeches, with warm fomentations at first, and complete rest of the foot for about twenty days afterwards, having constituted the most important parts of the treatment.

The bones of the leg are greatly exposed to all injuries likely to produce fracture, and such cases form a large proportion of those that are met with in ordinary practice.

It is not usual to find the fibula broken, and the accident unaccompanied with other injuries; such cases occur occasionally, however, and I have seen a well-marked instance of the kind where the bone
was broken about four inches below its head, by the person falling upon the margin of a step, so as to squeeze the outer part of the leg forcibly against it. In such a case there is little or no displacement, and the fracture can be discovered only after very careful manipulation; there is no necessity for splints, as the tibia affords the most complete support, provided the patient is careful to give the limb rest. The fibula is sometimes broken in the lower third, whilst the tibia remains entire, and the injury is often attended with severe contusion; but experience testifies, that unless a fracture or displacement of the tibia exists at the same time, there cannot be much separation between the fragments of the fibula. Occasionally the malleolus externus is split across, and as there may be little or no displacement, while at the same time the parts are by no means moveable, the most careful manipulation will scarcely serve to detect the sort of injury; but the most common seat of fracture in this bone is about four inches above its lower extremity; and here the displacement is generally considerable, as the accident is almost invariably attended with dislocation of the tibia inwards on the astragalus, or, as the injury is sometimes called, luxation of the foot outwards. The kind of injury referred to will be best exemplified by figures 195 and 198, in the preceding Chapter on Luxations. The displacement is commonly occasioned by the weight of the body pressing the tibia downwards after the fibula has been broken. The internal lateral ligament of the ankle-joint giving way, allows the malleolus to project, although in some instances this process is broken off close to the shaft of the tibia, and remains nearly in its natural position. In the latter event, however, the distortion may be less remarkable than is represented in the drawings. In either case the injury is a complicated one, as the ankle-joint is involved: yet it is satisfactory to know that serious results rarely follow; for, with the exception of a certain amount of thickening and stiffness, and, even in the worst cases, with a slighter degree of prominence than that represented in sketch 198, no ultimate inconvenience remains.

The tibia, notwithstanding its great proportionate bulk, is, from its functions and exposed position, much more liable to fracture than the fibula; and though I believe it is less frequently broken by itself than some imagine, this injury will, doubtless, constitute the most important feature in the case. The bone may give way in any part of its extent; the malleolus internus may be broken off by itself, as usually happens in the different displacements of the foot already described, or it may be complicated with fracture of the fibula, as already explained, and well illustrated in figure 212. Sometimes it is shattered into various portions in its lower
third, as was the case in the next example (fig. 213), taken from a patient of mine who died some days after the accident. Maceration caused the fragments to separate, but during life there was no such displacement, and the annoyance did not seem greater than might have been expected from a violent sprain. The preparation was kept chiefly with a view of satisfying certain sceptics, who, without such a proof were put before them, might contend that a vertical fracture cannot take place, although such an occurrence here, as well as in the upper end of the bone, at the condyles of the femur, and indeed, in almost every bone, must be admitted by every one familiar with the pathology of such injuries. In one instance the fracture will run straight across, or in another it will be more or less oblique; sometimes the skin and other soft parts will be lacerated, and the bone laid bare, or a fragment, usually the upper one, will project through the surface; again, the contusion and destruction of all the textures may be such as to render recovery impossible, and the ankle-joint, as has already been stated, or even the knee-joint, though this happens but rarely, may be implicated. I have said that in a fracture in the leg, where the solution of continuity is discovered to be in the tibia, it will constitute the most important feature of the case; and, indeed, unless the fracture in the fibula be very palpable, I deem it cruel towards the patient to make any particular examination, which might put him to additional pain to ascertain the fact; for a knowledge that this bone is also broken will not make the case appear much more serious in the eyes of the surgeon, nor will it cause any material difference in the method of treatment. I have often heard the question put, "if," in a case of fracture of the tibia, "the fibula were also broken?" and I have not deemed those who had set the limb less skilful nor less worthy of confidence because they could not give a precise answer; undoubtedly the tibia may be broken whilst the fibula remains entire, but in such a case there evidently cannot be much displacement; and in the majority of fractures in this situation, I believe that both bones give way, the fractures being either opposite to each other, as is seen in figure 214, or at a considerable distance, as in figure 215, where the tibia is represented as broken a few inches above the ankle, and the fibula near its upper extremity. It is in such an example as this last that the difficulty of detecting the injury of the latter bone is found to be greatest; and here, too, it may at once be perceived that the accident to the fibula bears a very trifling proportion to the more palpable and formidable fissure in the tibia: indeed, in this instance, the condition of the fibula was not known till examination after amputation, which was performed many weeks after the accident, in consequence of the
injurious effects of phlegmonous erysipelas. Figure 212, on page 336, was considered a simple fracture above the malleolus externus; gangrene supervened, and it was only after amputation that the tibia was discovered to be injured. In the case illustrated by figure 214, the fracture, besides being compound, was otherwise so palpable, that there was no doubt that both bones had suffered. These cases occurred in my own practice years ago in Edinburgh, and the specimens, with many others illustrating the same subject, now form part of the collection at King's College.

Many different methods have been devised and recommended for the treatment of fractures in the leg, and each plan has had its advocate as being superior to all others. Experience, if common reflection does not, will point out to the young surgeon, that what may answer well in one case will not do so in another; and, indeed, the circumstances are so different, in the various cases of this kind which may come under his treatment, that he will soon have reason to feel astonished that certain methods should have been recommended in preference to all others, as being best adapted for the treatment of all fractures in this part. In one instance he will find that the treatment may be conducted satisfactorily without the slightest trouble, and in another that all his care and ingenuity cannot avert unpleasant or unfortunate results; there may be serious contusion and injury of the surrounding soft parts; there may be laeration of the skin, and compound fracture; the fissure in the tibia may be oblique, and the fragments, two or more, may have a constant tendency to become displaced; there may be great irritability of the muscles, particularly during the early part of the treatment; great restlessness of the patient, or unwillingness to submit to requisite confinement,—in short, a variety of circumstances likely to cause difficulty in the treatment, or, at all events, to induce an unprejudiced practitioner not to persist in any individual method, when common sense, or the ordinary principles of his profession (the two ought to be deemed synonymous), should point out to him that some other plan must be pursued. Sometimes a fracture may be treated without the aid of any appliance; on other occasions, what may be deemed the most perfect apparatus will not enable the surgeon to be so successful in his treatment as he could wish; and here, in
acCORDANCE with the general object of this work, I deem it a duty to
direct the attention of the junior part of my readers to the chief
reasons for resorting to the use of apparatus or splints, in the treat-
ment of fractures, as I am inclined to believe that false notions are
occasionally entertained of their real purpose and value. The chief
purpose of a splint is to enable a surgeon effectually to keep the
fractured surfaces of a broken bone in the closest apposition during
the time requisite for reunion, and its value will consist, in great
measure, in the manner which it does so, and in the protection which
it gives to the limb against the various casualties to which the latter
may be exposed during the treatment, either from muscular contrac-
tions, from sudden and unexpected movements on the part of the
patient, or from external sources. The daily practice of surgery, or a
slight acquaintance with pathology, points out that the fragments of a
broken bone will unite without the aid of splints; but a conclusion
should not be drawn from this, or from the fact that instances may be
frequently seen where fractures in the leg are treated without them,
that all cases of the kind should be managed in the same manner;
nor, on the other hand, should it be supposed that such a machine has
any other effect, when properly applied, than the purposes briefly
pointed out above. It may perhaps appear supererogatory to remind even
my youngest reader, that nature alone effects the formation of callus
and the union of the fragments, and that a splint is of no further value
than what has been already stated, or, in other words, than giving that
degree of rest and security to the fragments which experience has
proved to be so essential to the well-doing of a fracture: I have been
induced, however, to be thus explicit, as it has occasionally appeared to
me that some persons (even in the profession, I am sorry to say) have
had no very clear notions of the actual, and merely mechanical utility
of such apparatus.

In all fractures of the leg, whether of the fibula or tibia individually
or of both; whether there is displacement, or not even an inclination
to it; and whether the fracture be compound or simple;—in short, if
the limb be in any condition such as to induce the surgeon to make an
attempt to save it, I decidedly give the preference to that form of
apparatus so ingeniously improved by Mr. Amesbury, by the late Mr.
M'Intyre, of Newcastle, and to the still more simple form recommended
by Mr. Liston, which latter seems well calculated to supersede all others
hitherto in use in the treatment of such injuries.

The splint (fig. 216) consists of a thigh and leg-piece of sheet iron,
and a foot-board of wood; the former are joined to each other by a
couple of hooks, and a screw, which is so placed that the two plates
can be set to any angle at which it may be desirable to bend the knee,
and the foot-board is fixed in such a manner that it may be slid
upwards or downwards to suit the length of the leg, and fastened by a
side screw in any position that may be desired. At the lower end of
the machine, there is a cross plate of iron, which is so attached that in
the event of the foot being raised or depressed, it will always rest
flatwise on the mattress, or a board placed at the foot of the bed, for
the purpose of supporting it. In treating a fracture of the leg with this apparatus, the patient must be kept in bed for three or four weeks at least, however favourably union may seem to go on, and proper regard should therefore be paid to his comfort during this irksome confinement. With a down or feather bed it will be almost impossible to keep the limb and body in a satisfactory position, and a hair mattress will best suit the object in view. But here I may call attention to the method of swinging fractures described a few pages further on. By such plan it may be in the surgeon’s power to add considerably to his patient’s comfort.

Previous to placing the limb on the splint, the latter should be covered on its upper surface with a folded towel, of a corresponding breadth, which should extend from the point of the foot-board to the extremity of the thigh-piece: a thin wool or hair cushion may be used instead; the object of either being to protect the skin from being fretted. The limb, slightly bent at the knee, may now be placed on the splint, with the ham resting opposite the junction of the leg and thigh plates, care being taken to apply such a degree of extending force as shall bring the fragments into the most favourable position:

Fig. 216.

these things being done the foot-board should next be placed against the sole, and fastened at the most convenient angle; a calico bandage should then be applied so as to fix the foot, leg, and thigh, to the whole apparatus; and in doing this it may be necessary to stuff in little pads of tow, lint, cushions of hair, or folds of cloth, between the towel and the splint, or to place some of these in front of the leg, to facilitate proper adjustment.

If the pads and cushions can be dispensed with, the handiwork will always look neater, and possibly, too, the surgeon will have less trouble in the re-adjustments, which their presence will almost always render frequently necessary: in many instances, however, they seem absolutely required, not only to assist in keeping the fragments in proper apposition, but also to prevent partial pressure, either from the weight of the limb, or the tightness of the bandages.

In some examples it is desirable to leave that part of the skin over the injury uncovered for a time, probably eight or ten days; and in all cases of compound fracture, where supputation may be expected, this is clearly requisite; indeed, in many examples the surgeon must be guided more by peculiar circumstances which may require cor-
responding treatment, than by any general rules which can be set down in such a work as this.

By comparing the limb with its sound neighbour, a tolerably correct idea may be formed as to its shape; and when once all the parts are properly adjusted, it rarely happens that much future trouble is experienced: on this score, however, much will depend on the nature of the fracture, the patient's condition and constitution, as well as upon those exigencies and casualties to which every one is at all times more or less exposed, and which, one and all, may serve to make the treatment difficult, to retard it, or even to set at nought the best efforts of the surgeon.

From day to day the position of the fragments must be carefully examined; occasionally a bandage must be loosened or tightened, or some little change may be necessary to obviate undue pressure on any particular point. The heel suffers most in this respect, and injury is best obviated by a just adaptation of stuffing under the lower third of the leg, by which the weight of the limb is diffused over a great extent of surface, instead of being allowed to press upon one part only. It is customary to keep the knee slightly bent, this attitude being most agreeable to the patient; but it will occasionally be perceived that the broken end of the upper fragment has a tendency to rise, and, by fretting the inner surface of the skin, endangers the safety of the limb by exciting suppuration and ulceration. I have known simple fractures thus converted into compound ones, and in several instances have seen the worst possible results ensue.

To obviate the dangers above alluded to, the foot should be placed nearly on the same level as the knee; the leg, from the knee downwards, should be kept a little above the level of the sound limb by placing a square block of wood under the lower end of the splint; or it may be found most convenient to keep the latter almost straight, and allow it to rest on the mattress. In the early years of my practice I was induced, from education and example, to consider the double-inclined plane as the most eligible method of treating all such fractures as have lately been referred to; within these thirty years, however, I have often had good reason to doubt the advantage of this system in all cases, as well as to admire the comparative comfort afforded to the patient, by placing the whole limb, from the hip downwards, nearly on the same line with that of the sound side. The apparatus above recommended will answer in any attitude which will be found most convenient, whether as a double-inclined plane, as a horizontal one from the knee to the foot, or from the hip downwards: the screw will regulate the relative positions of the leg and thigh plates, and by having the foot-board so constructed that it can be made, at the will of the surgeon, to slope outwards or inwards, in either of which positions he can counteract any tendency to displacement or twisting in the opposite directions, the apparatus seems to me as simple and efficient as any with which I am acquainted. I have often thought that an erroneous idea is prevalent that such a splint can only be used with propriety when the knee is kept in the bent position; but, from what
has been stated, it will be observed that it may be used under any circumstances.

In certain fractures it will be found difficult, with the ordinary footboard, to prevent the toes turning outwards or inwards, particularly in the latter direction; but with one, such as has lately been adapted to this splint, having a kind of hinge near the heel, which permits of lateral movements, these difficulties will be more readily overcome than by the usual means of pads placed alongside of the foot, which here, as in other parts of the limb, always convey a certain aspect of clumsiness and insecurity, by no means agreeable to the eye of the practised surgeon. I have made use of this foot-board for many years at King's College Hospital, and deem it a considerable addition to a splint already so generally efficient. In most examples of fractures of one or both bones of the leg, little or no trouble is experienced in keeping the foot in its natural position, as it may be but slightly, if at all distorted; in many, however, particularly if the distortion is chiefly occasioned by actual dislocation at the ankle, it may be very troublesome indeed to prevent the toes from turning inwards or outwards.

With the common foot-board, a pad on the inner or outer margin of the foot is, with the additional aid of the roller, the only means in the surgeon's power to keep the foot aright; but, without meaning to deny that the best of cures may be accomplished in this way, I am confident that lateral movements in the foot-board will be found highly advantageous, when there is great disposition for the toes to turn inwards or outwards.

In fractures of one or both bones of the leg, accompanied with partial or complete dislocation of the foot at the ankle, as described in previous pages, the above apparatus with the common foot-board, or that just recommended, will almost invariably produce every good result which the surgeon can desire. Notwithstanding the utmost care, the malleolus internus will sometimes be found to project considerably inwards, after union has been completed; and this condition may be attributed in some degree to the deficient means of extension afforded by the ordinary splints in use: but on this subject I must refer to the description, in a future page, of a form of apparatus which will in a great measure, in my opinion, obviate all further difficulty on this score.

With slight modifications in the adjustments, all fractures of the leg, whether with or without dislocations at the ankle, may be most efficiently treated as directed above; and although, from my own experience, I give these means a preference, it must not be concealed from the young reader, that there are many others in constant use among different surgeons, whereby at the end of the treatment the skill and tact of the practitioner is evinced in a manner equally satisfactory. As it is not within the scope of this work to describe, or even to enumerate all these methods, I must refrain from doing so, even were it in my power, or within the compass of my knowledge, to point out all the little differences in apparatus and in treatment which may be witnessed in a cursory glance at hospital or private practice in different
parts of the country. I cannot, however, omit referring particularly to two other plans, which the surgeon may occasionally, from necessity or desire, resort to with every prospect of advantage.

The splint above described may not be at hand, but a very simple substitute may be provided with little difficulty. A piece of wood, cut in this shape (fig. 217), forms the splint, which proved so efficient

in the hands of Dupuytren: its length should be such as to extend from the knee to four inches beyond the foot: its breadth about three inches,—thickness about half an inch. When properly laid along the inner or outer margin of the leg, it gives sufficient support to the fragments; and, being placed opposite to the side on which the foot is thrown, the distortion can be remedied with a few turns of the bandage between the foot and the projecting end of the splint. A thick cushion is required between the leg and board, particularly towards the ankle, both to fill up the natural hollow on either side of the limb here, as also, by separating it from the foot, to give a better purchase over the distortion. The limb may be kept straight, or it may be bent at the knee, after the fashion recommended by Pott for fracture of the femur.

A surgeon may often find it convenient to use a splint of this kind, and the ample experience of Dupuytren sufficiently attests its utility; but the fragments cannot be considered so securely placed as when the injury is treated on the machine first recommended. I have occasionally seen, in using this board, that it was difficult to keep the lower fragment and the foot in a proper position, and it has seemed to me that, either in the bent or extended position of the limb, there has been a disposition in the fragments to project forwards at the seat of fracture, over which it has been difficult to exercise sufficient control.

Within the last thirty years, many surgeons, particularly among our continental neighbours, have advocated a method of putting up fractures of the leg, by means of bandages and starch, in such a manner as to obviate the necessity for any of the ordinary splints or other more cumbersome apparatus. The fragments being properly set, the limb is enveloped, from the toes to the knee, by many turns of a calico roller, which is wetted with a thick solution of starch: when the latter becomes dry, a firm case is thus formed around the leg, which fits it accurately on all sides, and prevents any future displacement. The chief advantage claimed for the plan is, that, instead of the patient being kept in bed during four, five, or six weeks, as in the ordinary method of treatment, he can be allowed to move about the apartment almost as soon as the starch is dry.

In simple fracture of either bone, I have frequently used this method, and the results have been satisfactory; but it is difficult to imagine

Fig. 217.
that the practice will be either safe or efficacious in all instances, and the merits claimed for it seem so slight in comparison with the manifold advantages of other plans, that I cannot admit its superiority. The method is but little used by surgeons in this country excepting in the last stages of treatment, when it affords a valuable and safe means of abbreviating the tedious necessarily attendant on the operations of nature. In a simple fracture of the leg, when three weeks have elapsed during the use of some other plan; when all chance of severe inflammation and further swelling has gone off; when the first effects of contusion and laceration have subsided; when the fragments have got in a manner fixed; and when the patient is getting weary of confinement in bed,—there will be every reason to feel satisfied with such a measure, and instead of keeping him the full term of five or six weeks on his back, I strongly recommend the adoption of this practice.

Drawing 218, taken from one of my patients in King's College Hospital, will show the appearance of the leg in such a case: in this instance the person was kept in bed with his limb on a M'Intyre's splint for three weeks, and then, the bandage being applied and hardened, was allowed to move about with the aid of crutches, for the next fortnight, when the case was taken off, and a simple roller used instead for a short time further. In several instances where there seemed but little disposition to ossicle union, the patients have been permitted to move about with greater freedom than usual, with the leg thus enveloped, and desired at the same time to put the foot pretty firmly to the ground. The results have been very satisfactory. Instead of starch several other glutinous materials have been used. Common glue or liquid plaster of Paris will answer the purpose; dextrine has been especially recommended; or, what answers as well, equal parts of chalk and a thick solution of gum arabic.

In the plans above advised, I have occasionally found difficulties to be overcome, and deficiencies in the apparatus, which must be noticed by all who follow similar methods of practice. For example, in fractures of the tibia, a degree of extension is sometimes required, particularly in compound cases when the under fragment is drawn behind the upper one, which cannot be well applied with M'Intyre's splint, whether bent or straight. It is also often difficult to prevent the toes turning inwards or outwards; and it seems to me that the
foot-board, with the lateral movement, such as has been recommended at p. 342, might be advantageously combined with some such simplification of Desault's as that spoken of at p. 354, whereby an apparatus might be produced well adapted for all the ordinary examples of these accidents in the lower extremity, whether in the bones of the leg, the patella, or femur. Mr. Weiss has constructed an instrument, so simple both in its form and application, and at the same time so likely to be efficient, that I think it well worthy of fair trial. Figure 219 presents an outline of this splint: the bars and foot-place consist of

![Fig. 219.](image)

iron, the screws of brass; the long bar is of an average length to extend between the knee and beyond the sole of the foot; the foot-board is so attached that it can be slid upwards or downwards at will, and then be fastened by the side-screw; it can also be moved in a lateral direction, so as to evert or invert the toes; and, moreover, it can be placed at such distance from the splint at the ankle as may be found best suited to the thickness of the patient's limb. The cross-bar below prevents the member from rolling outwards or inwards, and by means of the screw, the side-splint and foot may be raised or depressed, as may be found most convenient. This bar may be attached to the screw at the knee, where it will sometimes be found to answer best; or two may be used, one above and one below, each being of service to raise the part over it to any required height. In the cut a small portion of another side-bar is exhibited; this is of the same size and shape as that above described, and is intended to act as a thigh-splint, in cases of fracture of the femur, or when it may be desired to apply extension in fracture of the leg. It can be firmly attached to the other portion at the knee; and when the upper end is fastened to the trunk by a circular strap, and another under the perineum, as with Desault's apparatus, the whole, though apparently much more slender, is equally firm, and as secure as can possibly be required for the generality of cases. Pads and bandages similar to those applied with the splints above described must, of course, be used here also.

Figure 220 is from a cast before replacement, where the tibia and fibula were broken; I had it taken with the object of showing the kind of distortion which occurs in some of these cases. Drawing 221 exhibits the same limb two months afterwards. It is intended to show that, with care, the projection of the upper fragment may be entirely avoided, and also is a good example of what may be done with the above splint, which was used on this occasion.
Since 1842 I have frequently used this instrument, and am still favourably impressed with its utility. In certain cases where the long bar has appeared somewhat slender, I have had a broader one con-

Fig. 220.        Fig. 221.

structed, and to give the limb an equable support on the lower surface, I have had it placed on a bag of sand so disposed as to have the desired effect. Figure 222 represents the leg with the apparatus applied. The tibia was in this instance broken about its middle third.

Fig. 222.

With simple fractures in the leg I have for a number of years given preference (as I may call it) to side splints of this shape (fig. 223), made of light fir. One has been applied on each side of the leg and foot, or perhaps one has not had the foot part, as represented in the lower part of the cut, and it has seemed to me of little consequence to which side the splint with the foot part has been applied.

In certain instances it is extremely difficult to continue the extension required to keep the lower fragments in proper position, and possibly the straps referred to at p. 354 might be advantageously applied. Some years ago Mr. Henry Greenway, then a pupil at King's College, devised an ingenious apparatus for the purpose of applying
extension in such cases, but its expense would be more than practitioners in general would care to incur, considering the various means already at their command for the treatment of such cases.

Fig. 223.

In concluding my observations on fractures of the leg, I cannot omit again referring to the method of swinging the part, after being properly put up with splints and bandages, although the practice has already been adverted to in the introductory Chapter on Fractures. Its chief advantage seems to be, that, when the patient moves his body in any way, as when the bed-pan is placed under him, the whole limb hangs in such a manner that the fragments are less likely to be disturbed than under ordinary circumstances. An admirable plan for effecting this object, is to suspend the limb with splints from the inside of the cradle, as it is called, which is usually placed over an injured limb to keep the bed-clothes from it, by means of two or three pieces of strong tape or leather attached to the arch.

Mr. James Salter, when house-surgeon at King's College Hospital, had an apparatus made similar to that above referred to, with some additions, which contributed greatly to the advantages of the system of swinging. It is here (fig. 224) represented as if in use for a simple fracture of the leg. The outside and larger parts of the apparatus will be recognised as in most respects like a common metal cradle, but at the top will be seen a strong and smooth bar of iron, on which a couple of pulleys rest; these glide readily along the bar, and there is a hook attached to them below, to which, by means of a chain, a case for holding the leg is attached. When the leg is placed in this case, it will, in slight movements of the body, swing from the hook by means of the chain, and in larger movements—as in using the bed-pan, or taking a new position in bed—the pulleys will roll upwards and downwards, so that there is no probability of the fragments gliding upon each other, or the seat of fracture being in any way disturbed. The length of the chain permits free lateral movements. The case below
is so constructed that various parts of it can be unhked, to permit dressing to be applied in instances of compound fracture. I have had under notice ingenious contrivances similar to the above, devised by Mr. Alfred Roberts of Rye, and Mr. Henry Greenway.

Fig. 224.

This apparatus is almost in constant use in King's College Hospital, both in simple and compound fractures of the leg, and it has invariably been of great comfort to the patients. In some instances where it has been resorted to, after the limb had been allowed to rest for days in the bed in the ordinary way, the relief which has followed has been very gratifying. In some diseases of the foot and ankle-joint, as also of the knee, when it has been of much consequence to give the greatest possible rest, I have seen it of much service. I may now add, in the year 1870, that the favourable opinion heretofore entertained of this apparatus is equally strong.

The patella is frequently broken, the injury being in general the result of violent action of the muscles in front of the thigh, as when a person endeavours to prevent himself from falling forwards whilst the knees are bent: if, at this time, the bone comes in contact with any opposing object, fracture is likely to occur. It is often difficult, however, to account for the exact cause of fracture, although the nature of the injury is very readily appreciated. The bone may be broken into various portions, or merely divided into two; the fissures may be perpendicular, oblique, or transverse: in the former instance there is seldom much displacement; but in the latter the space between the fragments may be from half an inch to an inch, and, if the treatment be neglected, even this distance may become greater. In the vertical fracture, the fragments are not under the direct influence of any muscles, unless from a few fibres of the vasti, so that whatever displacement there is must arise chiefly from the force which may have
occasioned the fracture, or from the effusion of sero-synovial fluid into the joint which usually follows this injury. In the transverse fracture the lower fragment keeps its natural position, whilst the upper is separated by the action of the quadriceps extensor: here, too, the separation is often made more extensive by the increase of fluid within the joint.

Figure 225 shows a transverse fissure, such as that where separation may become extensive, and the other (fig. 226) is partly oblique and partly vertical. In this specimen ossific union had occurred.

Although in these cases the lacerated wound of the joint is always followed by considerable inflammation, swelling, and effusion, it rarely happens that the articulation is permanently disabled; and so long as there is no external aperture, there need be little fear of the result. It will be observed that a split of this bone, even when the skin over it is entire, cannot altogether be considered a simple fracture, for the injury is complicated with division of the synovial capsule; but fortunately it is rarely followed by very severe consequences: even in the event of wound in the skin also, unless the injury be otherwise very formidable, the best hopes may be entertained of saving the limb.

The treatment, in what is called simple fracture, which, in my opinion, may almost invariably be pursued, is to place the limb upon a Mc'Intyre's splint in a complete state of extension, with the foot raised a few inches above the level of the hip, and the shoulders and trunk somewhat elevated too, in order to relax the rectus femoris as much as possible: a folded towel should be laid lengthwise between the skin and the splint, and for the first few days it may not be deemed requisite to apply a bandage of any kind, unless in instances when, from the restlessness of the patient or other causes, there is a risk of the limb falling off the apparatus. All movement at the joint is prevented by the splint, and the parts are kept much more steady than even on the hardest mattress. At first leeches and warm fomentations may be applied, or cold lotions, according to the apparent extent of inflammation; and, as the absorption of fluid within the joint begins and progresses, a bandage may be used to restore the displaced fragment to its natural position. As soon as it is perceived that acute inflammation has subsided, and the fluid within the capsule has diminished, a simple roller must be carried round the limb and the splint, from six or eight inches above the knee, as low as the tuberosity of the tibia: to effect more complete downward pressure on the upper fragment, it will be well to place a pad of lint along the lower part of the rectus. As the effusion subsides, the bandage must be tightened from day to day, until, probably on the tenth or twelfth, the fragments will be brought into approximation, without causing the
slightest pain,—and now the pressure by the roller may be made of a firmer and more permanent kind.

Among the various contrivances for approximating the fragments I may mention two circular belts of leather, one above, the other below, the knee, which can be drawn towards each other by straps. Mr. Wood, when house surgeon at King's College Hospital, suggested a simple apparatus which proved very suitable. A flat plate of about five or six inches broad, and, in most respects, like a M'Intyre's splint, seeped on one side to fit to the limb, was provided with two hooks, as represented in this sketch (fig. 227), one above and one below, which had the effect of keeping the bandage steady when drawn in the figure 8, and allowed more efficient pressure to be made upon the upper fragment.

I cannot say that good results have invariably followed, having met with examples where it was found impossible in any way to get close union: but, after all, it seems to me that surgeons have made a kind of bugbear of the bad results attendant upon non-union of a broken patella; for the dissecting rooms and daily practice afford ample proof that, although the upper fragment be separated from the lower for an inch or more, the loss of power is wonderfully little. These observations are not made by way of sanctioning any carelessness in the treatment, but rather to prevent the young practitioner giving himself much distress because he cannot bring about a close approximation of the broken surfaces. Some time ago we had a patient in King's College Hospital, whose limb is accurately represented by the accompanying figure (228); even here, although the condition was the same in both limbs, the person seemed not to be conscious of much inconvenience; but it was apparent that
he had not the same muscular power in his thighs as he must have had at an earlier period of life before the injuries happened. The tissue between the fragments in these cases becomes remarkably strong, and answers tolerably well the purposes of the ligamentum patellae. Mr. William Adams kindly displayed to me some of the specimens of this condition, which he examined anatomically, and from which he has drawn the conclusion that a new fibrous structure does not form except in cases where the fractured surfaces are close to each other. When the fragments are far asunder, the intervening tissue seems thin and chiefly composed of the aponeurosis and tendons of the vasti muscles.

I had under my care, in our Hospital, an unusual case of fracture of this bone. About five years before the patient broke the patella, and the fragments remained an inch separate: on being brought into the house for an injury of the same knee, it was found that the lower fragment was broken transversely, whilst the newly-formed ligament above was uninjured.

In other fractures of the extremities, I am an advocate for replacing the fragments at the earliest possible date, instead of waiting until inflammation and swelling have subsided; but in fractures of the patella, as the chief resistance to approximation seems to arise from the presence of fluid in the joint, I prefer waiting until it is absorbed. There are some instances where the disturbance within is so little, that a tight bandage may be applied almost immediately after the accident.

Malgaigne proposed to hold the fragments together by hooks stuck through the skin into the bone, so attached by a screw or screws that they could be approximated. I have known the plan answer well, but it is painful, and I have seen a fatal result from inflammation produced by the presence of the hooks.

In compound fracture of the patella, the injury to the neighbouring parts is sometimes so great that the surgeon cannot hesitate about the necessity for amputation: occasionally, in giving the patient a chance to save the limb, the extent of inflammation, and its consequences—suppuration and ulceration—are ultimately such as to demand this last resource, though in such instances a fitting time for its performance may never occur, and the patient sinks, but on the other hand, the most happy results will sometimes follow this complicated injury. Shortly before I left the Royal Infirmary of Edinburgh, a patient came under my care with a compound fracture of the patella, occasioned by striking the knee against the sharp corner of an iron lamp-post. She was immediately conveyed home, and the edges of the wound in the skin were brought together with adhesive straps, whilst the limb was placed in the extended position. The accident happened about eight o'clock p.m., on the 8th of February, 1840, and on her admission next day, at one p.m., her pulse was slow and feeble, her extremities cold, and there was great general depression. On examination, the patella was found fractured transversely about its middle, and there was a wound on the surface, about an inch and a half in length, running in the same direction a short way below the fracture,
THE INFERIOR EXTREMITY.

On percussion, a considerable quantity of air was detected in the joint, in consequence of which the wound, which had partially united, was opened, and the air was pressed out. The limb was then placed on a straight Mc'Intyre's splint, the heel raised, and cold applications made to the wound. A fluid like synovia continued to ooze out for many days. This patient (aged about forty) had considerable fever, and smart local inflammation, for the first four or five days, but ultimately made an excellent recovery: on the fourth of March the fragments were in good apposition, and in eight days more she was dismissed cured.

Towards the end of treatment in a case of fractured patella, when the patient is allowed to stir about on crutches, the movements of the knee should be restrained with bandages or other convenient apparatus. In private practice, nothing will answer better for this purpose than the laced and elastic knee-caps, which, now-a-days, are so admirably constructed from leather or of caoutchouc in its different forms.

As somewhat analogous to the above different injuries, I may here refer to rupture of the ligament of the patella, and also to that of the united tendons of the rectus and crureus muscles. The former occurs very rarely, and, the same may be said for the latter,—an example of which, however, came under my notice some time ago in the person of a young gentleman, eighteen years of age, who, in saving himself from slipping backwards on the pavement, felt a sudden snap at the knee, and was immediately after unable to extend the leg excepting with great pain and a severe effort. On examination about an hour after the accident, I could distinctly feel a space an inch and a half above the patella, where the separation existed. A splint of wood was adapted to the back of the limb to secure extension, and care was taken in applying a roller to place a pad along the foremost part of the thigh, to retain the end of the rectus as low down as possible. The recovery was more rapid than after fracture of the patella, and the limb ultimately became as strong as its fellow. In such a case, or in the instances where the ligament of the patella is injured, the practice should resemble that which is required in fracture of the patella,—the extended position and rest being the main features.

I have seen an instance of neglected rupture of the tendon of the rectus and crureus above the patella. The injury had happened four or five weeks before, and the gentleman being of active habits, had walked about notwithstanding pain and lameness. There was now a gap nearly an inch in extent, between the ruptured ends, but this could be diminished by a little pressure. Here I proposed to make the surfaces raw with subcutaneous incision, and then to treat the case as if of recent date, but the patient was content to let the parts remain as they were.

The femur may be broken in almost any part of its extent: and, as in other long bones, the fissure may be transverse, oblique, or nearly perpendicular; the fracture may be simple, compound, or
FRACTURES OF THE FEMUR. 353

complicated, and the bone may be divided into two, or there may be many fragments. Perhaps the most common seat of fracture is about the middle (fig. 229), and in this situation the fissure is usually transverse. The bone at this part is so covered on all sides, that compound fracture occurs rarely in the middle of the thigh: the femur from which this sketch is taken was thus broken, however; but, although compound fracture is occasionally seen even higher up, it most generally happens towards the lower extremity; upon the whole, however, the accident is rarely met with, compared with the frequency of the simpler form, occurring in any part of its shaft, from one end to the other. If towards the lower extremity, the condyles may be so separated from the shaft, by oblique or perpendicular fissures, as to involve the knee-joint, and thus render the injury complicated; and if at the upper end, the head may be so divided from the neck and shaft that ossific union can scarcely occur, and the limb can therefore never again acquire anything like its original strength:—but before alluding particularly to fractures in the neck of the bone, I shall treat of those lower down, which, if not of more frequent occurrence, are, at all events, more worthy of the surgeon's consideration, from the circumstance that they usually happen at that period of life when active exertion is of more consequence subsequently than in the individual of advanced years, in whom the neck of the bone is so apt to give way, but whose physical capabilities have already been well nigh exhausted.

Fracture in any part of the femur below the trochanters is of most common occurrence when man may be said most to require the full use of his limbs, and it therefore becomes of vast importance to effect a cure with the fragments so adjusted, that there may be the smallest possible extent of either deformity or loss of power. The thigh is almost invariably shorter than its fellow: in a simple transverse fissure immediately above the condyles, the surfaces are so extensive that their complete separation is of rare occurrence; but in oblique fracture here and in other parts of the bone, the lower fragment may be drawn upwards, and shortening may be considerable. From the multiplicity of forces which occasion fracture, the rough ends of the fragments may pass in any direction: if the displacement be not great, the limb may be merely bent at an obtuse angle, with the part below slightly twisted outwards or inwards; but, perhaps, the most frequent displacement is that where the end of the lower fragment passes behind the upper, when the latter is usually said to ride over the former. Perhaps the particular cause of fracture, the weight of
the limb (as the person is being carried after the accident), and muscular action, may all conduce to this form of displacement. I believe the latter influence is most at work, for, in addition to the effects of the psoas magnus and iliacus internus in raising the upper fragment, the long muscles extending between the pelvis, and the lower end of the femur and upper part of the leg, along the back of the thigh, are most likely to act with great force on the lower fragment in drawing it upwards and backwards,—a force against which the powerful muscles in front, from their less advantageous position, offer but a feeble resistance. The lower fragment does, however, sometimes pass in front of the upper; it may, indeed, go in any direction, but it is most frequently behind.

If there is displacement, in whatever direction it may be, and whatever may be the amount of distortion, one of the first and grand objects of treatment should be to bring the fragments as nearly into their natural position as circumstances will permit: if this is done, and due care be taken to keep them thus, the rest of the sanative measures may be left to nature. Numerous methods have been followed by different practitioners in the treatment of these fractures. It is seldom that there is any difficulty in extending the limb sufficiently, provided this be attended to soon after the injury has happened, before inflammation has begun, and the muscles and other textures have become in some degree habituated to their new and unnatural conditions. Sometimes, however, particularly in the upper third of the thigh, when there has been extensive effusion of blood, it is difficult to draw the limb to a proper length, until part of the fluid has been absorbed and the swelling has somewhat subsided. I have seen some instances where eight or ten days have elapsed before sufficient extension could be made, and remember one example of fracture below the trochanters, where probably some of the perforating arteries had been torn through, and where the tension of the skin was so great from the amount of effusion, that no attempt could reasonably be made to bring the limb to its proper length until after such lapse of time as rendered any interference useless. Coaptation is generally more difficult and more troublesome to accomplish than mere extension: and as there is a constant tendency to distortion, the surgeon must have a careful watch over the appearance and attitude of the limb for the first ten or fifteen days of treatment.

The methods of Pott and Sir Charles Bell—resting the thigh on its outer side, or bending the limb to a double incline at the knee (referred to in former editions of this work) are in a manner out of date, and the simple modification of Desault's splint, recommended by Liston, seems to me to be largely in favour.

The splint consists of a piece of wood similar to that referred to at p. 343, but longer, broader, and stouter, according to the bulk of the limb on which it is to be placed: it ought to reach from the side of the chest to four inches beyond the foot: a pad of folded cloth, or cushion of horse-hair, extending along the inner side nearly its whole length. Coaptation being properly produced, and the patient extended
on a hard mattress, the splint, with the cushion next the skin, should be laid along the outer side of the broken limb; then, with some turns of a roller, the foot and ankle should be fastened to the notched extremity below, the surgeon taking care that the limb is in a natural position, with the toes turned neither too much out nor in (the appearance of the other foot always guiding him in this respect); next a folded handkerchief, with perhaps a little tow, wool, or hair wrapped up in it, to prevent its galling the skin, should be so applied, that, whilst its centre rests in the perineum, one end passes under the hip and the other in front, both meeting at the two openings in the upper end of the splint: when passed through these, a noose should be cast, and, by tightening it, the splint, with the lower part of the limb—which has already been fixed to the board by the bandage round the ankle,—will be thrust downwards, the pelvis being the fulcrum, and thus will the extension be kept up during the after treatment by occasionally tightening the handkerchief: the next and last step in the proceedings is to apply a roller from the ankle upwards, when the limb will present the appearance represented in fig. 230.

Fig. 230.

Sometimes it may be advantageous to place a short wooden or pasteboard splint along the inner side of the thigh, and, if the fracture be low down in the femur, there is not much occasion for the band under the perineum, as the purchase of the splint and bandage on the upper fragment is sufficient to keep all steady.

In fracture of the lower third of the bone or in the upper or middle part of the tibia, I have seen a method like the following answer most excellently: while in the country, on a holiday trip, I have in my younger days (being then an adept with the saw and plane) gone to the nearest carpenter's shop, and cut out a couple of splints similar to those above referred to; I have then, after setting the limb whilst the patient was in bed, rolled them up in each side of a double table-cloth, until there was just space enough left in the middle to contain the limb, which was next placed between the boards, and retained steadily by bringing the splints up on each side, and keeping them there by means of a sufficient number of stout tapes. This method I first saw used by my friend Mr. Stuart, of Kelso, a most excellent and experienced practitioner; and, having since tried it frequently, I can speak very confidently in its favour.

Fractures of the neck of the femur have been distinguished into those which occur within the capsular ligament, and those which take place outside, and the principal point of difference between the two is,
that in the latter the fragments may be expected to unite by bone, whilst in the former such an event rarely happens. There is no part of Sir Astley Cooper's admirable work on Dislocations and Fractures more worthy of notice than that which relates to this subject, and his experience and investigations have been such, that, coupled with the additional observations of the editor of the last edition, Mr. B. Cooper, it is scarcely possible to refer to any feature in such cases which has been overlooked by these distinguished authorities.

Between fractures anywhere in the vicinity of the trochanters, provided they are outside of the capsular ligament, and those in other parts of the shaft below, I cannot see any great practical distinction: undoubtedly they happen near to these processes more frequently in the person advanced in years than in one who is under the middle age; yet, as I have myself seen, they may occur at the age of twenty-two, and in no respect need treatment different from what might be deemed requisite in that part of the bone below the trochanters,—the object being, in either case, to keep the limb at a proper length, in good position, and to procure ossific union. Though all these ends cannot be accomplished in every instance, it is, in most, quite proper to keep them in view. But the leading features of practice may be different when the fracture is within the capsule, and hence the necessity of forming an accurate diagnosis before the treatment is actually begun.

Although age is by no means a certain criterion of judging of the exact position of a fracture in the upper part of the femur either within or without the capsular ligament, and though Mr. Stanley has recorded a case of fracture of this bone, within the hip-joint, at the age of eighteen, it must be admitted that those in its neck, particularly within the capsule, are of rare occurrence under the age of fifty. Out of two hundred and twenty-five cases which Sir A. Cooper calculated he had seen in public and private practice during a period of thirty-nine years, he had only seen two cases of fracture in the neck of the bone within the capsule under that age, and during the same period he had only once seen a dislocation of the thigh at the age of sixty-two. These statements, then, ought to be very conclusive on this point; and when a person above fifty,—especially above sixty, and of the female sex, has met with an injury of the hip attended with symptoms of fracture, the chances are that it is within the capsule.

The injury is usually the result of a fall, and may be appreciated with tolerable accuracy by the following circumstances and symptoms: the advanced period of life, the patient having pitched on the trochanter or hip, and being immediately afterwards unable to move the limb without great pain, are all sufficient to excite suspicion of what has happened: when he is laid in bed, the toes are pointed outwards; the whole limb upwards to the trochanter major is everted; it is half an inch, an inch, or more, shorter than its fellow; the trochanter is less prominent than on the other side, and nearer to the crest of the ilium; if the limb be turned inwards, it will of its own accord soon resume its everted position; the knee is usually straight; the whole muscles
of the member seem to be paralysed; the patient makes no effort to move the part; and, if desired, seems incapable of raising the thigh by calling the psoas and iliacus into action; if, added to all these, there is crepitus, there need be little doubt about the nature of the injury. Crepitus is not easily felt on all occasions, even when there is fracture: the manner in which it can be best detected is by desiring an assistant to draw down the limb, a proceeding which is very easily accomplished, and then, by pushing the trochanter towards the acetabulum, and rotating the femur on its long axis, the rough surfaces can be felt grating against each other. It must be confessed, however, that this sensation is often detected only after considerable manipulation and much pain to the patient, but in modern time I have experienced much assistance from chloroform during such an examination. The absence of, or difference in, one or more of these symptoms, should neither null suspicion nor alter the diagnosis: thus, shortening of the limb is not always present, as there may be fracture without displacement. There is in my collection a fracture through the cervix femoris, yet during life there was no shortening, no eversion, and, moreover, no crepitus. Sometimes, instead of eversion, there has been inversion; but this is exceedingly rare, and occasionally, although, perhaps, with equal rarity, the toes have been seen at one period turned out, and at another turned in, in the same case.

Most of these symptoms are equally apparent in fractures through the trochanters, and also in the neck of the bone immediately above, as in instances within the capsular ligament; and if there be great obesity, or much swelling from effusion and inflammation, it will be impossible to detect the exact seat of fracture: but in some cases, as with thin old women immediately after the accident, the shaft of the bone can be so distinctly traced, in its entire condition, to the top of the trochanter, that, if there be fracture at all, it must be near the head; and if the circumstances and symptoms are as have been stated above, there can scarcely be a doubt that the injury is within the capsule:—I say within; for, although it may be partly within and partly without, and whether or not the fragments are still held together more or less firmly by the reflected ligament within the capsule, the practical deduction should be, that the fracture is one which in all likelihood will never unite by bone.

I know of no authority so much to be relied on for the truth of this doctrine as that of Sir Astley Cooper, who, in referring to his own vast experience, ranging over a period of forty years, after having seen two hundred and twenty-five cases of supposed fracture in the neck of the thigh-bone, and examining many preparations of the kind obtained from his own practice and that of others, states, that in these examinations he had only met with one example in which a bony union had taken place in transverse fracture of the cervix femoris entirely within the capsular ligament. Sir Astley, like other authorities, does not deny the possibility of union in such a case, but doubts its probability. Like many of my contemporaries, I have seen several well-marked examples of ossific union in the neck of the femur; but there is always
a doubt whether, in these cases, the fracture was entirely within the ligament or only partially so; and whether, even in bearing the marks of having been in such a situation, the reflected ligament and periosteum had been entirely divided. In the event of either of these membranes being more or less entire, there is greater chance of union than when they are completely torn through; for, in the latter event, the only remaining course for circulation in the head of the bone is through the round ligament, and this narrow channel may be deemed as only sufficient to support the vitality of the part, but not to add new growth.

The remarkable frequency of these injuries in aged females, compared with their occurrence in man, must have been observed by all who have had experience. It is usual to attribute the facility with which the fracture happens to the natural change in the direction of the neck of the bone, which is the result of advanced years. In youth it shoots obliquely from the shaft, but in old age it passes off from between the trochanters, almost at a right angle; sometimes the trochanter major is actually above the level of the head of the bone, and it is by no means uncommon to find the neck shorter, and even less in diameter, than in the early or middle periods of life. It is evident that in the erect position the weight of the trunk must, in the young person, be transmitted through the femur more directly in the long axis of its neck, and that under such circumstances it must be capable of supporting a much greater weight than when passing horizontally between the trochanter and the acetabulum; but at any period of life, so far as I know, the fracture never occurs when the patient is upright: it happens during a fall on the hip or trochanter, at which time it may be supposed that the weight of the pelvis is supported more directly in the long axis of the neck than at any other; I have, therefore, often doubted whether or not these alterations in the line of the bone have much influence in the production of fracture, and have been more inclined to attribute their frequent occurrence in old age to the friable state of the bones at this period, as also to the circumstance of the neck, from its thinness and cellular character, being the weakest part: and if in all these views I am correct, the frequency of the accident in females may be reasonably attributed, ceteris paribus, to the greater projection of the trochanter in them, from the width of the pelvis, than in the male subject. If, however, the fracture occurs in consequence of the limb being twisted under the other, as it generally is in a fall on the trochanter, then, of course, the altered line of the neck of the bone above referred to must render the part particularly liable to the injury.

The diagnosis of fracture in the upper part of the femur, or in the neck of the bone, is usually so clear, that one cannot but be astonished at the occasional mistakes which are made, by confounding such injuries with dislocations at the hip. Figure 231 gives a fair illustration of the most conspicuous appearances; the aspect of age, compared with that at p. 327, of a figure with dislocation on the dorsum illi, at once points out one of the most
distinctive features between them; and a slight study of these figures, with the symptoms peculiar to each case, will show how wide the differences are. Drawing 232, which exhibits a fissure through the neck of the bone within the capsule, and also the displacement of the shaft, both upwards, and as regards eversion, gives further illustration on this subject. In many instances, however, the distortion which ultimately appears is far from being distinct at first. It often happens in such cases that the capsular ligament remains tolerably entire, and prevents any immediate displacement likely to be very conspicuous or easily detected. In modern times I have found chloroform of great service in facilitating the diagnosis of some of these cases.

The treatment of this fracture may be conducted with the thigh bent at the hip, or in a straight position; the latter plan seems most in repute, and, as in other parts of the limb, I generally give it the preference. The splint, bandages, and manner of setting the limb, are all such as have been described and exhibited, at p. 354, in reference to fractures lower down. It is not, however, in all instances that the subsequent course should be the same: in very aged persons, and when there is but little displacement, it may be doubted whether or not a splint should be applied at all; in fractures of the shaft of the bone, no such doubt can or should be entertained, for ossific union is almost certain to follow, and a splint is of infinite service in keeping the fragments in their proper position; in the neck of the bone, however, no such union can reasonably be expected; and as any kind of apparatus, such as splints and tight bandages, may be exceedingly troublesome to some patients, nay, actually productive of harm, and
as no ultimate benefit can be expected from persistence in their use, the propriety of applying them at all may well be taken into consideration.

At first the shortening and continued disposition to an increase of it, as also the tendency to further eversion, may be efficiently counteracted by a splint including extending force; but after the parts have set, as it were, in this way, and after the acute pain and inflammation,—the necessary result of the injury,—have subsided, the sooner a little movement is made the earlier will a false and callous joint be formed, and the patient begin to make some use of the limb. Some of the best results I have seen in these cases have been in examples where, from the first, I have declined to use splints, but have encouraged movement within the first forty-eight hours.

When the splint is removed, the knee and hip may be slightly bent, and a pillow put under the former, to give it support; as soon as the patient is inclined to leave his bed, he may be permitted to do so: at first he must support himself with crutches; by-and-by a stick may be substituted, and, with the additional aid of a high-heeled shoe, he may afterwards move about with great ease and security. In such instances, as I have had frequent opportunities of witnessing, on inspection after death, the broken surfaces of the fragments become absorbed to a greater or less degree; become hard and enamelled where they are opposed to each other; the textures around thicken, and form a kind of new capsule; occasionally even some new bone is deposited on various parts in the vicinity; and the obturator externus and other muscles attached to the digital fossa, behind the trochanters, become considerably increased in bulk and strength.

The above method cannot be accomplished in some cases, and in others it would not be correctly applicable; thus in certain individuals the tightness of the bandage around the ankle is sufficient to threaten or induce sloughing, and in others similar effects are produced by the band under the pelvis; sometimes there may be positive objections to this plan, from the state of the ankle or perineum; again, if the patient is aged, otherwise infirm, and likely to be little capable of using or requiring the limb in any active exertion at a future period, it may not be thought proper to harass him with any incumbrances, or at all events the advantage gained (if any) will not be equivalent to the vexatious restraint; but, on the other hand, if the patient be comparatively young and stout, and if there be the least idea that the fracture is such that bony union may be reasonably looked for (as in the neck of the bone outside of the capsule), then the use of the apparatus should be persisted in for five or six weeks at least.

The double-inclined plane has been recommended in these cases as well as others in the lower extremity, and by some it has been thought advantageous to place both limbs in a similar attitude: the angle of the two planes is made so high, or, in other words, the thigh-boards are made so long, that the pelvis hangs from the knees, as it were; and, whilst extension is thus kept up, the surgeon has the opportunity, by keeping the knees together, of ascertaining that both thighs are much
FRACTURES OF THE FEMUR.

about the same length. Instead of using a couple of splints, two boards of wood, of sufficient breadth to sustain both limbs, have been put together at a proper angle, and used on these occasions. The same plan has been sometimes used, too, in fractures of the shaft of the femur; but it is evident that the upper fragment cannot be considered as at all fixed by this apparatus; and when ossific union is expected, I should not be inclined to recommend it, though aware that good cures have followed this method, as well as others. I have noticed, that under such treatment the feet and legs have become remarkably oedematous, unless well encircled by bandages, and there has been altogether such an apparent want of comfort and security in the plan, that, excepting under particular circumstances, I would never resort to it.

It will be remarked that in every fracture of the lower extremity I have invariably recommended the straight position, which with few exceptions, will, I believe, be found the most satisfactory method; the surgeon may, however, see good reason occasionally for rejecting it, and, it need scarcely be added, that whichever practice be pursued, there is much need of care, both in putting up the limb, and in the after-treatment; its length, attitude, and general contour, must each and all be carefully attended to; and I feel satisfied that the sooner all this is done after the injury has happened, so much the better for both patient and surgeon.

In fractures of the lower extremity during the period when the patient requires to keep his bed, a space seldom less than five weeks, and often much more, and when it is of great consequence to keep the fragments still, the urinal and flat bed-pan are of essential service. Some surgeons have objected even to the use of the pan, however, and beds have been constructed with apertures in the ticking and framework below the pelvis, with the view of permitting the patient to evacuate the bowels without the necessity of raising the body at all. Earle's bed is the most celebrated of this kind; but, unless in Bartholomew's Hospital, I am not aware that it is much in use among our hospital surgeons, who, with occasional exceptions, seem mostly to prefer a well-stuffed hair-mattress, and to trust the care of the patient to the attendants. Within the last twenty years, during which I have generally made use of the swing apparatus, described at p. 347, for fractures in the leg, I have rarely seen much inconvenience in using the ordinary bed-pan. This, in my opinion, is an important feature in the system of swinging fractures.
CHAPTER IV.

LIGATURE OF ARTERIES.

Ligature of one or other of the arteries of the inferior extremity is of common occurrence on the living body, and such operations should be practised on the dead subject.

Spontaneous aneurism is rarely seen in a vessel of the magnitude of the anterior tibial: it may, however, be the seat of false aneurism, resulting from a wound; or in such an injury the external hemorrhage may be great, and either example may require the interference of the surgeon. Again, it may be deemed advisable to ligate the artery in consequence of severe bleeding from the sole of the foot; or, in other instances, to restrain the growth of, or obliterate, aneurism by anastomosis in this region.

In the example of aneurism resulting from a wound, if the tumour is not large, and there be no complication or circumstance to induce the surgeon to act otherwise, I imagine there can be little doubt that cutting down to the vessel at the seat of the disease, through the aneurismal swelling, sponging out the blood, and placing a ligature above and below the orifice in the same manner as for varicose aneurism in the arm, is the proper practice to be pursued; but in an instance of wound of this vessel in simple fracture, as might possibly happen, such a plan would be very questionable, as the fracture would thereby be rendered compound; here ligature of the vessel higher up, if such a step were practicable, or of the femoral, would perhaps be the best proceeding. The tumour may, however, be large, or the blood may be extensively extravasated through all the soft textures: it may be doubtful whether it will be better to cut into the swelling under these circumstances, or to restrain further bleeding by ligature above: again, when the anterior tibial is opened by wound, the injury done to the bones and other parts may actually induce the surgeon to amputate the limb.

In cutting down to the vessel in the case of a wound bleeding from the surface, or in the instance of opening the aneurismal swelling, after a sufficiently free aperture has been made in the integuments, the stream of blood will perhaps be the best guide to the bleeding orifice. It will be proper to apply the tourniquet on the thigh, and if there is any difficulty in detecting the vessel, the pressure may be relaxed, when the blood will flow. In either of these cases the incisions on the surface must be made in the immediate vicinity of the wound in the vessel; but, in other examples, the surgeon may have a choice of parts through which he may cut. Over the arch of the foot the vessel may be readily exposed; indeed, it lies so near the surface in this situation, that I have known it divided by a surgeon whilst making incisions through the skin in the treatment of erysipelas: an incision, an inch and a half or two inches in length, should be made over the most convex part of the foot, commencing a little in front
of the ankle and extending as far as the space between the metatarsal bones of the great and second toes: after the skin is divided, the strong aponeurosis immediately underneath must be cut nearly to the same extent; the tendons of the extensor pollicis and extensor longus communis muscles will now be exposed, and the vessel will be found lying between them in close contact with the bones, accompanied by a vein on each side: a slight scratch with the point of the needle will allow these vessels to be put aside; then, the ligature being carried round the artery and fastened, and the edges of the wound approximated by one or two stitches, the operation is completed. Occasionally, in this situation the vessel will not be found exactly in the space between the tendons above named: it may take a slight turn under the common extensors ere it dips between the metatarsal bones, and it should always be remembered that it may possibly be wanting altogether.

In the dead subject such an operation as that described is very easily accomplished; but in the living body, unless the parts are free from swelling, whether from inflammation or infiltration of blood, the same facility should not be expected.

The vessel may be secured above the instep, by making an incision three inches in length, and searching still between the tendons already named: if, however, the incisions be made more than a hand-breadth above the ankle, the artery must be looked for between the extensor pollicis longus and tibialis anticus; low down, it lies on the surface of the tibia,—higher up, on the interosseal membrane.

In the upper third of the leg, the vessel lies deep between the last-named muscle and the extensor communis, and a free incision of the surface will be required to get to the bottom of the space between them: the aponeurosis of the leg offers a greater obstacle to exposure of this deep space than the integuments; it must, therefore, be divided to an equal extent, and, in addition, a little transverse notch in it on each side of the wound will greatly facilitate the proceedings. Throughout its course in the leg the vessel is accompanied by two veins; but, here, as in the foot, the anterior tibial nerve is so far separated from it, as not to be much in the way; and, indeed, its division with the knife would be of no great consequence. Sketch 233 exhibits the lines of incision: on the lower part of the leg the wound should be about three-fourths of an inch on the fibular side of the
crest of the tibia; higher up, particularly if the subject be muscular, it should be an inch and a quarter at least from the same part, to make allowance for the breadth of the anterior surface of the tibialis anticus; and in each proceeding, especially that high up, the surgeon should not make his way between the muscles directly backwards, but should follow the line of separation between them, which leads inwards towards the centre of the limb.

In attempting these operations it should be remembered that the artery is occasionally irregular; it may be very small, or it may, as has already been stated, be wanting altogether: neither a bleeding wound nor an aneurism on the dorsum of the foot, though the vessel can actually be felt pulsating in front of the ankle, will with certainty denote its presence in the usual situation higher up; for, when it is deficient in size or absent, there is commonly a large branch of the fibular passing through the interosseous ligament, a little above the ankle, to the fore part of the leg, which occupies the site of the anterior tibial on the foot.

The circumstances which may demand ligature of the posterior tibial artery will be similar to those requiring deligation of the anterior, and the remarks in reference to the rules of practice are equally applicable. If the surgeon has a choice of situation, he ought undoubtedly to select that part of the vessel where it lies between the malleolus and calcaneum. An incision, two inches in length, should be made midway between this process and the insertion of the tendo Achilles: after the skin has been divided, some strong aponeurotic fibres must next be cut in the same manner, and the artery will be found immediately beneath, accompanied by two veins, with the posterior tibial nerve between it and the os calcis. Perhaps, however, the vessel must be sought for higher up, and four inches above the ankle an incision may be made through the skin about three inches in length, and half an inch posterior to the margin of the tibia. The knife should be carried through the aponeurosis; for, in this situation, both the superficial and deep layers are so nearly in contact, if they are not actually, that they may be considered as one, when the artery will be found on the flexor communis and tibialis posticus muscles: a vein will be perceived on each side, and the nerve nearer the fibula. Even within four inches of the ankle, the solcus may be found covering the vessel, and higher up it is almost certain to do so: the muscle being irregular in this respect, the operator may be prepared to meet with some of its fibres in the lower third of the leg; but, however easy it may be on the dead subject to expose the vessel by cutting through this muscle, the operation might be difficult on the living body. A good anatomist can have little trouble in making an incision of three inches in length, parallel with the vessel, and half an inch behind the margin of the tibia, dividing skin, superficial aponeurosis, solcus, and deep fascia, so as to get upon the vessel as it lies on the deep layer of muscles: all this he may do with ease on the subject; but to accomplish such proceedings on the living body, he must be a cool and dexterous operator, and one not likely to be
LIGATURE OF ARTERIES. 365

annoyed at the continued oozing of blood from the bottom of the wound, nor likely to be scared either by the deep gap in the limb, or the tediousness of the operation.

Instead of dividing any part of the soleus near to the tibia, by making the wound in the skin so close to this bone as has been directed, and thereby avoiding the gastrocnemius muscle, it has been recommended to search for the vessel through a wound made nearly in the middle of the calf. In a thin subject, by cutting in the upper third of the leg, midway between the fibula and the inner margin of the tibia, dividing the skin for four inches, also the inner heads of the gastrocnemius and soleus muscles, with the fasciae, superficial and deep, the vessel may be exposed; but I should certainly not feel inclined to attempt such an operation on the living body, even though it be sanctioned by such a high authority as Mr. Guthrie. In an instance of extravasation of blood, or aneurism from a wound, an attempt might be made to get at the vessel through free superficial incisions; but it appears to me that all stated above regarding the operation on the inner side of the limb is equally, indeed even more, applicable here; I cannot, therefore, recommend such proceedings; and if a vessel must be tied so high up, probably the safety of the patient, and his ultimate comfort, will be best secured by ligature of the superficial femoral artery.

The peroneal artery can scarcely be imagined to be the seat of spontaneous aneurism; and it lies so deep, and so protected by the fibula, that a wound in it must be of rare occurrence. The vessel may be reached through an incision, three inches long, and parallel with the posterior border of the bone. If the wound be made about the middle of the leg, some portion of the soleus must be divided, and the flexor longus pollicis may either be turned towards the fibular margin of the gap, or its fibres may also be cut across: on the dead subject, the latter may usually be preferred, and I believe it would be better to do the same on the living. The vessel is often so small, that I have again and again seen it missed in dissecting-room operations. If the incisions are made higher up, possibly some fibres of the outer head of the soleus will be divided, and after the division of the latter, the deep aponeurosis alone will intervene; but it is here so thin, that it may escape notice. I can hardly, however, imagine the necessity for any such operations in ordinary surgical practice.

Considering the irregularities of both the posterior tibial and fibular arteries, I cannot but repeat my objections to attempting these proceedings on the living body, in the upper third of the leg, by the Hunterian operation,—that is, by cutting down on either of the vessels above an aneurism or wound: the necessity for doing so on the fibular is, as already stated, scarcely to be imagined, and the same may almost be said regarding the posterior tibial: indeed, I have for many years looked upon such proceedings as appertaining so much to mere dissecting-room displays, that in my lectures I have only referred to them because they have been described by anatomists, more, in my
opinion, to show what may be done with correct anatomical knowledge, than with reference to what might be considered good surgery. In the lower part of the course of the posterior tibial, a ligature may occasionally be required, and this sketch (234) will show the lines of incision as above directed.

Now, after forty years experience, I feel bound in this edition, probably the last I can personally supervise, to reiterate that these so-called operations on the tibial and fibular arteries are suggestions from the dissecting-rooms more than of the practical surgeon. It may be from lack of opportunity that I have never seen one or other of these operations needful, but now I venture to hint to future writers whether they shall continue to reprint suggestions or descriptions about things which rarely, if perhaps ever, occur in the practice of surgery on the living body.

Ligature of the popliteal artery for aneurism is seldom, perhaps never, performed in the present day. Previous to the introduction of Hunter's operation on the superficial femoral for aneurism of this vessel, the surgeon was in the habit of cutting into the ham, clearing out the contents of the sac, and tying the artery above and below its communication with the disease; but such a proceeding is now never contemplated; and as the vessel is so well protected against injury, it will rarely occur that the surgeon has to secure it for a wound in this situation. The artery may be exposed by an incision, about three or four inches long, between the ham-strings, and parallel with its course. The patient should lie on his face, and the wound should be nearer the inner than the outer ham-string: its upper extremity should be four inches above the condyles: two inches above the innermost of these processes the artery will be found close upon the surface of the bone; but before it can be reached, after the division of the skin the aponeurosis must be cut to the same extent, and nearer to the vessel, some cellular texture, fat, and perhaps a lymphatic gland or two, must be divided or held aside. The vein and artery lie in close contact, surrounded by cellular membrane, which forms a kind of sheath to the vessels: the vein lies behind the artery, so that in performing the operation with the patient on his face, it will be first encountered; perhaps a small portion of the artery will be seen on the inner side of the vein, and the latter should be slightly turned to the outside, to allow the point of the needle to be carried between the two and round the former. The posterior tibial nerve (popliteal) lies so nearly in
the centre of the ham, that if the knife be carried close to the inner boundary of this space, as directed, it may not be met with at all, particularly if the incision is high: if seen, it should be held to the outside. If the operation is done as recommended, the vessel will be at a very considerable distance from the surface; higher up the distance is greater, and lower down it is less; but here the proximity of the posterior saphena vein, and the sural as well as the articular vessels, should induce the surgeon to avoid the part. Here again I beg to remind those who follow me of the observations on the preceding page. In reality I have never known an instance of ligature of the popliteal artery excepting in amputation.

The proposal of M. Jobert to cut for this vessel on the inner side of the limb, a little above the inner condyle, between the vastus and the ham-strings, seems to me another of those dissecting-room speculations which I have characterized above, and I need not, therefore, dwell on its merits or demerits.

The superficial femoral artery may be secured with a ligature in any part of its course. It has been customary to describe the operation in two places,—either in the middle of the thigh, or in its upper third: the first being similar to that which was done by Hunter, and the other like that recommended by Scarpa. In either the patient should be laid on his back, with the leg a little bent at the knee, and the thigh slightly rotated outward, and also bent upon the pelvis, so as to expose its inner and anterior surface. In the middle of the thigh a wound of three or four inches in length should be made parallel with the vessel, and nearly, therefore, in the same course as regards the sartorius muscle. The skin and subcutaneous cellular texture being divided, the aponeurosis should be cut to the same extent, when the fibres of the sartorius will be brought into view; its inner margin may next be turned outwards, as was done by Hunter, or its outer margin may be turned inwards, as has since been more recommended, and at the bottom of the space between the vastus internus and the adductor longus the vessel will be found: here it is covered by a slip of the tendon of the last-named muscle, which requires to be divided, when the vessel will be found in close contact with the vein, which, however, will probably be so completely behind as to escape observation: the saphenous nerve may be seen immediately in front of the vessel, or perhaps it may be noticed ere the slip of the adductor has been cut, for it sometimes lies in front of this texture, and at other times in immediate contact with the artery. The point of the needle may be passed on either side of the vessel which the operator may find most convenient, and should always be kept so close to it as not to endanger the vein. It has been said that, if this operation is done too near the aperture in the adductor magnus, there is a chance of coming in contact with the anastomotica magna, and, indeed, I have seen this vessel tied, on the dead subject, instead of the femoral, although I can scarcely imagine such a mistake occurring on the living body.

This operation may be somewhat more difficult than some might
suppose, for no particular guide can be given, unless it be the course of the fibres of the muscles. After the skin and fascia have been divided, and some muscular fibres exposed, it may be doubtful to which muscle they belong,—whether to the sartorius or the vastus: if to the latter, they will seem to run obliquely along the inner side of the thigh; and if to the former, they will pass more in its long axis. If the thigh has been placed as directed, and the first incision has been made about the middle of its breadth, the sartorius will assuredly be the muscle, and the future incisions may be made on either margin at the will of the surgeon, or if he chooses he may divide the muscle entirely, though, under ordinary circumstances, such a proceeding cannot be recommended.

Whether it is from the comparative depth of the artery in this situation, and also the comparative difficulty of the operation, or that the circumstances suggesting such a proceeding are more rare, I will not attempt to determine, but it is beyond doubt that the artery is not so frequently tied in the middle of the thigh as in the upper part of its course. In the different instances in which I have known it secured at its passage through the adductor magnus, the operation has been done for secondary hemorrhage in the leg, after amputation; I know of no particular advantage in selecting this situation, unless it be that in the event of secondary bleeding at the seat of deligation, there is still another chance left for the patient having the same vessel tied a little higher up; neither is there any great disadvantage, for I attach no consequence to the arguments that high inflammation with abscess or diffuse suppuration is more likely to follow here than nearer the groin: considering, however, that in the upper third of the thigh the vessel is much more easily reached, that there must be less disturbance of parts, and that the operation must be equally efficient,—I cannot but recommend the selection of the operation in this situation. The circumstance of secondary hemorrhage is one of much importance; yet, in my opinion, any calculations as to its probability of occurrence should not deter the surgeon from the operation above the sartorius, which seems to me, under nearly every circumstance, that which is most eligible. Here the vessel is to be secured towards the lower angle of that space so particularly described by anatomists as the triangle of Scarpa.

The operation may be performed in this manner:—The patient being placed on his back, with the limb bent as already directed, the surgeon should feel for the anterior superior spinous process of the ilium, and for the tuberosity of the pubes; nearly midway between these points he will discover the femoral pulsating, and about three inches below, in the line of the vessel, should commence his incision through the skin, and carry it downwards for three inches and a half, in a direction parallel with the axis of the limb, and consequently parallel with the superficial femoral: the skin being divided, the aponeurosis of the thigh will be readily exposed by division of the superficial fascia, and here, perhaps, a few lymphatic glands may be met with; the aponeurosis being next cut through, some fibres of the
sartorius may probably be seen, and the sheath of the vessels will be exposed: this latter texture being cautiously opened to the extent of a quarter of an inch, or less, the artery may be recognised, and the needle passed around it from within outwards, care being taken to keep the point so close to the vessel that there may be no danger of transfixing the vein.

If the first incision is placed as above directed, and if the operator takes care to go neither to one side nor the other, the vessel can scarcely be missed; yet I have known a surgeon pass an inch deeper on its inner side. The pulsations of the artery will form a good guide in general; and when there is any difficulty, a reference to the sartorius muscle will be of service, provided the incisions have been made sufficiently low to expose its fibres. In this situation, as in most other parts of the body, I believe, as has already been stated in the introduction to this work, that a knowledge of the appearance of textures is of the greatest value in enabling the surgeon to complete the operation in a safe and satisfactory manner.

The internal saphena vein may possibly be seen in the first incisions, and should, of course, be carefully avoided; but the wounds, either in the upper or middle third of the thigh, should be made sufficiently towards the mesial line as to avoid this vessel. The saphena nerve is generally on the outer margin of the artery, outside of the sheath, and away from the reach of the surgeon; if, however, the operation be done very close to the sartorius, it may possibly be in the way, and should be carefully held to one side. The vein is partly on the inner side of the artery, but chiefly behind it: too much care cannot be taken to avoid this vessel in using either the knife or the needle: the edge of the former should be applied cautiously in dividing the sheath, and the point of the latter, being first insinuated between the vein and artery, should, as has already been advised, be carried outwards in close contact with the last-named vessel. Many examples have been known of injury of the vein in this operation, and have been referred to by Cooper, Carmichael, and others: I have myself seen one instance where the point of the needle as it was carried round the artery was thrust through the vein; the hemorrhage was copious on the instant, but as soon as the ligature was tightened (no attempt was made to alter its position) it ceased, and although that patient afterwards died of phlegmonous inflammation and secondary hemorrhage,—which of the two was the immediate cause of death it was difficult to say,—I cannot attribute the fatal result to this mishap, yet I must, nevertheless, repeat my caution to avoid the vessel. In another example, I had reason to suppose that the point of the needle had injured the main vein or a branch, mortification of the foot supervened, and the patient's life was saved at the sacrifice of his limb. In an instance in which Sir Charles Bell cut down upon this artery in the usual manner, and placed a ligature upon it, the pulsations in the tumour continued, and it was afterwards ascertained that the vessel was double. No other similar case has ever been met with in practice, in so far as I know, but such an irregularity has occasionally been seen since in the dissecting-room.
Sketch 235 exhibits the lines of incisions above recommended, the under one showing where Hunter applied the knife, the upper being the situation recommended by Scarpa. For the convenience of displaying the lines, the artist has kept the limb in a straighter position than has been above described.

Secondary hemorrhage occasionally occurs after ligature of the superficial femoral artery, and, often, too, in instances where it might be least expected. Three examples have happened in my own experience, and in none of these instances was the artery disturbed in an unusual manner, or divested of its sheath to a greater extent than to allow the point of the needle to be passed; nor was the ligature placed nearer than an inch to the deep femoral. In such cases a question will arise regarding the course of practice to be followed:—If the vessel has originally been tied in the middle of the thigh, I should be most inclined to place another ligature on the same vessel higher up,—that is, several inches higher, above the sartorius; but if the operation has already been done in this situation, the question may be, whether the vessel should be again tied at the same place, or that a ligature be cast on the common femoral or external iliac.

If either of the latter operations be adopted, it will be observed that the circulation through the deep femoral will be obstructed, and that consequently there may be such a deficiency of blood in the limb afterwards as to end in mortification. In ligature of the femoral or external iliac, as a primary operation, such an event is of rare occurrence, but the circumstances are very different in the case at present under consideration: here not even the smallest quantity of blood can be expected to flow by the superficial femoral, supplied either by a retrograde current through the deep branch, or through the epigastric; whilst, in a primary operation on the iliac, this may reasonably be calculated on, even in an instance of aneurism in the groin,—the current at first being sufficient to give effective assistance to the other channels of circulation which support the vitality of the limb below, but yet not so strong as to prevent the favourable changes in the tumour, which tend to the cure. In secondary bleeding from the superficial femoral, the retrograde circulation referred to above must be prevented by pressure over the bleeding orifice and the course of the main artery, otherwise, even after ligature of the external iliac, the hemorrhage, though checked in its impetuosity, might still continue to an injurious extent. In one instance, however, Sir Philip Crampton successfully applied pressure over the pubes.
Ligature of Arteries.

In one of my own cases, on the sixteenth day after deligation of the superficial femoral in the groin, a ligature was applied to the external iliac, and also slight pressure in the groin over the course of the open vessel, to check secondary bleeding: these had the desired effect; but mortification of the whole limb, from the foot to the hip, speedily ensued, and death was the result. The loss of vitality seemed at first to be confined to the lower part of the limb, and I was, therefore, induced to amputate in the thigh, but the stump, within twenty-four hours, became similarly affected. I confess that I should feel reluctant to follow this practice in a similar case, and I should be more inclined to place ligatures immediately above and below the bleeding orifice, though such a proceeding is doubtless somewhat equivocal also. In such a course pressure should be applied upon the common femoral artery by the thumbs of a steady and trustworthy assistant; then by enlarging the orifice in the track of the original wound, the artery should be exposed, separated slightly from the vein, and secured with threads. But such operations are more easily talked about, and described on paper, than done on the living subject; the person who attempted such a practice as that referred to, would require great coolness and confidence in his own resources, as well as considerable nicety in manipulation, and supposing infiltration of blood to have taken place, much difficulty might be anticipated in accomplishing the object immediately in view.

In making a selection of either course of procedure, the practitioner will assuredly feel himself in a most eventful dilemma: if the patient is let alone, loss of life must be the result; and pressure, if it be tried in such a case, may be uncertain, and probably unsafe too; for if it be sufficient to stem the current in the artery, the vein will be compressed also: how, and what to do then, he will have difficulty in deciding, and whatever course he may think fit to pursue, the patient's safety must be considered in the utmost jeopardy.

Ligature of the common femoral artery is seldom performed now-a-days. It was done before Mr. Abernethy performed his first operation on the external iliac artery, and has since been recommended by some as a preliminary step to amputation at the hip-joint. For the latter purpose I do not consider it at all necessary, and for aneurism the superiority of the operation on the iliac seems so great that there cannot be a doubt which should be selected. On the dead subject the vessel may be easily displayed by making an incision in its course about three inches long, the upper end of it being a little above Poupart's ligament: the skin and superficial fascia being cut through, the aponeurosis of the thigh should be cautiously divided about an inch below the ligament; the sheath of the vessels should next be opened with equal care, and the artery being slightly denuded, should be surrounded with the needle, the point of which should be carried from within outwards; for though there is a slip of cellular texture between the two vessels here, the vein might be injured were the instrument carried in the opposite direction. A good anatomist may make the incision so strictly over the artery, that he will probably not
see the vein at all, as it lies on the inner side. The inguinal glands and the arteries connected with them may attract little attention; but on the living body they might occasion considerable trouble, and I have known them do so in operating on the upper course of the superficial femoral, as well as on the lower part of the external iliac. The trouble arising from these sources, then, more particularly from the divided arteries, as well as the proximity of their origins to the seat of ligature, as also of the pudendal branches, the circumflex and epigastric arteries,—the circulation through all of which might prevent the closure of the main artery, and, in addition, when it is considered that in the subsequent movements of the thigh, however slight, the artery is likely to be considerably disturbed,—all seem sufficient grounds of objection to this operation, excepting under very particular circumstances, and should induce the surgeon to give a preference to the external iliac for the seat of operation.

The operations on the continuation of these vessels higher up will be considered in the section on the pelvis, and here I deem it right to call attention to the Chapter on Aneurism in the first portion of this volume, where allusion is made to the revived method of treating this disease by pressure, a practice which, as applied to the femoral artery within these thirty years, has been attended with such signal success as to arrest and attract the consideration of all practitioners to the subject.

Of the sixty-one cases alluded to there, as having been published by Dr. Bellingham, forty were instances of popliteal aneurism and fourteen of femoral, and from these numbers we may gather the relative frequency with which the special mode has been adopted, and possibly too the relative frequency of external aneurisms wherein this mode of treatment might be advisable. In either view it seems evident that a large proportion is in the lower extremity, and I should deem this chapter far from perfect if I did not make special allusion to the subject, in conjunction with the descriptions above given, for ligature of arteries for the cure of aneurisms.

For either the popliteal or femoral aneurism the pressure may be made on the common femoral artery, or on the superficial. Sometimes one point may be chosen, sometimes another, and not unfrequently in one case both may be tried alternately.

The principal feature in all the instruments which have been used for such practice is, that while effectual pressure may be kept up on the main artery, the collateral branches throughout the greater part of the limb have free action, and the part below is sufficiently supplied with blood. Instruments similar to those which were used in the last century have been revived, and some modern improvements have also been called into play. I have seen the tourniquet of Signoroni (p. 28) used with admirable effect, and two of the successful cases in the tables given by Dr. Bellingham, were treated under my observation by my friend and former pupil, Mr. Robert Storks, with this instrument alone. I may here refer to Mr. Tufnell's "Practical Remarks on the Treatment of Aneurism by Compression,"
for an interesting notice of the various contrivances which have been used in Dublin in this mode of treatment, and for my present purposes it may perhaps be sufficient that I give a sketch of that which seems most in favour among the Irish surgeons. Figure 236 represents Dr. Carte's "Circular Compressor." In this instrument one pad only for pressure on the artery is depicted, but others have been devised, where two can be called into play. My friend, Mr. Bulley of Reading, devised a very effective-looking apparatus of this sort. As most patients complain if pressure be long continued on one spot, it can be relaxed on one screw and applied by the other, or both may be used at the same time in a modified degree, in accordance with the feelings of the sufferer. Whatever instrument is used it is of importance to bear in mind that the absolute stoppage of circulation is not essential, as it has been proved by experience, that a diminished flow is sufficient to effect the desired end. If, however, it is found that pressure strong enough to arrest the blood in the main vessel can be applied, then doubtless the favourable effects may be expected more speedily.

As a steady and, I hope, consistent advocate for compression in cases such as have been under recent consideration, I think it right to state that I have from time to time been disappointed in its effects. Within these two years I have had to ligature the superficial artery in three instances where pressure applied with all care was unavailing. Fortunately, in two of these the ligature was crowned with success.

Since the last edition of this work a novel mode of pressure has been specially brought under notice by Mr. Ernest Hart and Mr. Shaw, in papers read by them at the Medico-Chirurgical Society, and published in The Transactions, 1859. This mode consists in bending the leg upon the thigh; and the fact was, I believe, first noticed on a patient of mine in King's College Hospital, that pulsation in an aneurism in the ham could be arrested in this manner. Circumstances prevented a persistence in this treatment; but not long after, the gentlemen above named were each fortunate in curing a case in this way, and from time to time other instances have occurred. In
1864 Mr. Hart referred to the thirteenth case which had come at that date within his knowledge. I have noticed that in certain cases, even putting the limb in a perfectly straight attitude has had the effect of arresting pulsation in the tumour; but I am not aware that any success has as yet followed such an attempt at cure.

CHAPTER V.

APPLICATION OF BANDAGES AND STRAPS. OPERATIONS FOR VARICOSE VEINS.

REMOVAL OF FOREIGN SUBSTANCES FROM THE KNEE-JOINT.

Supposing a youth taking a course of instruction on the dead body, and anxious to make the most of a single subject, he should perhaps take into consideration certain minor operations which he may be called on to perform in practice. For example, in the treatment of ulcers of the leg, he will, even whilst a student, have to apply a roller from the toes to the knee; and should it happen that he is engaged in hospital duties, unless under a good-natured and indulgent teacher, he may possibly be more annoyed when he does not accomplish the proceeding in a proper manner, than he may anticipate.

For whatever object a bandage is applied, whether in the treatment of ulcers, of varicose veins, or of fracture, it is of importance to observe that an equal amount of support or pressure is afforded on all sides. In bandaging the leg the following method should be pursued: The end of the roller should be laid on the anterior part of the metatarsus, and two or three turns should be made upon the foot as high as the instep; next, a turn should be made round the leg immediately above the ankle, and round the foot again over the instep: as it is seldom thought requisite to cover the heel completely, the bandage may now be carried up the leg, turn after turn, until it is enveloped as high as the knee, or as far as may be required, each turn of the cloth being made to cover a third or more of the preceding, and as the swell of the calf increases, the roller should be reversed, or folded downwards, for by such a movement the pressure is equally diffused over the surface, and thus no inequalities will be perceived when the bandage is removed, but that an equal support has been given to the surface throughout. The method of applying a bandage is easily demonstrated on the body; but it cannot be so readily described: the following drawing (237), and a reference to that at p. 344, will serve to make my description more clear: the roller may be held either in the right hand or in the left, and carried from the right side of the leg or the left, at the will of the surgeon, as seems best fitted to the circumstances.

In old callous ulcers on the living body it may be deemed necessary, to give further support to the parts, to approximate their edges, and also to apply a certain amount of stimulus, by means of straps of adhesive plaster, from an inch and a half to two inches broad, and of
such a length as to encircle the limb. The middle of each strap should be placed on the side of the leg opposite to the sore, and each end should be brought forward and crossed in a sloping direction over it. In some instances it may seem best not to encircle the whole limb, but to draw the skin into approximation by placing the straps first on one side and then on the other, so as to draw the opposite surfaces of skin towards each other. In either way a sufficient number of straps must be applied to cover the limb an inch or more above and below the ulcer, and over all a calico roller should be placed as above described; but as this practice has already been particularly referred to in the Chapter on Ulcers, it is unnecessary to dwell upon it here.

The method by means of the roller (made of flannel, however) combined with the calamine cerate and compresses, constitutes that which was so highly extolled by Mr. Whately, and that, with straps and the calico bandage, forms the chief feature of Mr. Baynton’s practice. In modern times, cloth prepared with caoutchouc has been recommended as a good substitute for the flannel or calico bandage in such cases, and the latest fashion is cotton thread bandage worked in a manner similar to a stocking. The latter seems an advantageous improvement, possessing greater elasticity and more durable powers than the common calico; but the former, in so far as I can perceive, has not maintained the pretensions with which it was brought forward.

The treatment of varicose veins in the lower extremity, constitutes, in the present day, more of the surgeon’s duty than was formerly the case; for although at all periods of the history of the art it would appear that various operations were performed on veins, differing in kind and in severity, from the actual cautery to the simple puncture with a lancet, little active surgical interference was resorted to in the present century, until within the last forty years, when an important change in practice, with reference to varicose veins was proposed, and has been most extensively pursued. In consequence of the fatal results which once or twice followed the application of a ligature to the saphena vein, on the inner side of the knee, as practised by Sir Everard Home and others, surgeons seemed suddenly to have concluded that all interference with this vessel or its branches was fraught with the utmost danger; and notwithstanding the apparent success attending the division of these vessels, as practised by Sir Benjamin Brodie, it seemed to have become at once a settled point, that, excepting under most urgent cir-
cumstances, the only safe practice in varicose veins was by supporting the vessels and parts by means of bandages or laced stockings. Of late years, however, there has been ample ground for doubting the correctness of these doctrines regarding injuries of the veins; and although I do not wish to advocate any useless interference with these vessels, or any carelessness regarding them, in operations on arteries for aneurisms, or during amputations, I do not hesitate to state my opinion, that the dangers of some of these accidental or intended injuries have been much exaggerated. In illustration, the instances of interference with varieose veins, with which most modern surgeons are now very familiar, may be referred to. The examples afforded by the practice of Velpeau, Davat, Frieke, and many of our own practitioners, clearly evince the rarity of unfortunate results, or of dangerous consequences from local inflammation, induced by surgical interference. The discussion of such matters does not come within the scope of my present object, but experience convinces me that far less danger is to be apprehended from injuries to veins than the doctrines of forty years back inculcated.

The change consisted in operations with needles which may be performed as follows: whilst the patient is in the erect position, the outline of the vessels to be selected for the proceedings should be observed: he should then lie down, and the surgeon pinching up a vein, with a portion of the skin, between the fore-finger and thumb of the left hand, should with his right pass a needle, such as one of those delineated at pp. 52 and 53, straight across under the vessel; he should next twist a thread around the needle, as represented on this sketch (238), drawing it sufficiently tight to obstruct the circulation; he should then repeat the operation at other parts as often as may be thought advisable, and having cut off the ends of the needles, the limb will appear like the drawing (238), taken from one of my patients, wherein it will be remarked, that, besides a number of needles used according to the method now described, which is much the same as Velpeau's, there are some made to cross each other according to the plan of Davat. The latter consists in passing the second needle at right angles to the first: its point is thrust through the vein, above or below, then carried behind, and again made to transfix the vein in its passage to the surface; thread is then twisted around each needle, at the will of the surgeon, and the circulation in the vessel completely obstructed.

Fig. 238.
It will be perceived that in Velpeau's plan the vein is merely compressed between the needle and thread, and that in Davat's method it is twice transfixed; in the latter instance, therefore, as the injury is greater, the amount of inflammation likely to follow will be in proportion; and, as it is a principal object of the operation to induce the adhesive process in the site of the needles, the result may be more satisfactory, so long as the disease remains local. I have found Davat's method produce the supposed requisite amount of inflammation most rapidly; but the other, if persisted in sufficiently long, has been equally successful in its results. In some cases the needles require to be removed on the second or third day, and in others they seem to produce so little irritation, that they may be allowed to remain for a fortnight or more. As a general rule, they should be left until they have excited considerable swelling and slight ulceration; and in some instances, when the former is not very conspicuous, they may be permitted to separate by ulceration through both vein and skin. I recommend that the process of inflammation should be more implicitly relied upon than that of coagulation, either below a needle or between a couple of them; indeed, in many examples, it appears that coagulation does not occur, although, partly with a view to ascertain this, I have included an inch or more of the enlarged and distended saphena on the inner side of the knee, between two needles, and have, on withdrawing them before much inflammatory action was excited, discovered that the circulation has gone on immediately after, almost in as full a volume as before. Out of numerous instances in which I have resorted to this practice, I have not met with any seriously unpleasant effects; in one case only has there been a slight suppuration around the needles; but, as already stated, a cure has not been the invariable result: the practice, however, is an admirable addition to surgery; and, whatever may be the opinion ultimately formed by the profession of its utility in the treatment of varicose veins, there can be little doubt of its eligibility in instances of rupture of the enlarged saphena—an accident by no means of rare occurrence, and one which has been known to be the cause of speedy death from loss of blood. Years ago there was a patient in King's College Hospital, with varicose veins of the leg: she had been admitted in consequence of rupture of the saphena, in the site of a small ulcer. By rest in the horizontal position, and the usual lotions, ointments, &c., the surface healed, and the patient was dismissed cured, but she returned within a few days, the vein having again given way, and the cicatrix having burst; needles were then applied, and caused the obliteration of the vessel above and below the ulcer; when the latter was healed, the patient was again dismissed, and has since remained cured. Recently I have had under my care a similar example. Profuse bleeding occurred at the margin of an ulcer as the patient (a muscular man) walked along the Strand. The horizontal position sufficed to permit the closing of the vein and the ulcer, and the patient has not appeared since.

Occasionally the surgeon may deem it requisite to cut into the knee-
joint, for the purpose of removing loose cartilages; but being a
wound not to be thought lightly of, in so far as the safety of the
patient is concerned, it would be advisable to try palliative measures
before resorting to such a proceeding. The application of a common
roller to the knee, or any apparatus to restrain movements of the
joint, or to fix the loose substance in one position, where its presence
will not cause further annoyance, should first be tried; but if it is
then found that something more must be done, the cartilage should be
removed. The operation may be accomplished thus:—The patient's
limb should be placed horizontally, and the body should be slightly
raised to relax the extensor muscles in front of the thigh; by pressure
with the fingers, the loose object should then be worked to one side of
the patella, until it lies in front of one or other of the condyles of the
femur, and the internal should, if possible, be preferred; the surgeon
should then draw the skin slightly upwards, and keep the object
steadily fixed between the fore-finger and thumb of his left hand; he
should next cut boldly down upon it, with an incision of sufficient
length to allow it to escape, which it usually does by starting suddenly
through the wound,—a movement which may be much expedited by
gentle pressure with the points of the fingers. As soon as the sub-
stance is away, the skin should be allowed to resume its natural posi-
tion, when the aperture on the surface will be half an inch or more
below that through the synovial capsule. A strap or a little simple
dressing should be applied, and, to ensure perfect quietude for the next
eight or ten days, the limb should be kept steady with a splint.

I have met with a variety of instances where it has not been
advisable to resort to this practice; I have, however, in many cut into
the knee-joint in the way described with perfect success; and in these
examples, I attribute the absence of dangerous inflammation to the
great care which was taken, constitutionally and locally, both before
and after the operation. All the cartilages in these cases have been
small,—few bigger than a garden bean; but I have extracted much
larger with equal success, although I have known alarming inflam-
mation follow some of these operations.

To obviate the dangers of a large external wound, a method has
been proposed by Dr. Goyrand, as also by Mr. Syme, to remove these
bodies from the knee by means of subcutaneous incisions. The
object being fixed as above described, a narrow knife is passed under
the skin, and a wound is made in the capsule, of sufficient size to allow
it to be squeezed out of the joint into the subcutaneous cellular tex-
ture; time is then given for the wound in the synovial membrane to
heal, and the cartilage may afterwards be permitted to remain in its
new position, or removed through an incision of proper size in the
skin, according to circumstances.

Instances have been known where bullets, necrosed portions of bone,
and other foreign substances have been extracted from this locality;
but such proceedings are very different in character from those above
alluded to, as before anything of the kind has been attempted, the joint
has been in a manner destroyed by inflammation and its consequences,
and therefore they more resemble excisions of diseased portions of bone, than operations on a joint whose articular surfaces may be considered in a state of health, as is the case in the instance of loose cartilage.

The practice of puncturing the knee to permit the escape of fluid in cases of hydrops articular, has been spoken of familiarly by some foreign practitioners; but neither in Scotland nor in England, where this affection is by no means uncommon, have I ever seen an instance where such a proceeding could have been justifiable. Malgaigne has tried the plan frequently, but the results have been sufficient to show that such a method by itself is of little or no value: indeed, from all I can conceive of the practice, I should be very unwilling to resort to it. Were an opening deemed advisable, however, the same care must be taken to prevent the ingress of air as has been recommended above for the removal of loose cartilages; for doubtless the same amount of danger, if not a greater, attends upon such a proceeding, whether it be done with a knife, or by means of a trocar or canula, as some have recommended. In accordance with modern fashion, iodine has been injected in some of these cases by Bonnet, Velpeau, Jobert, and others. I have no personal experience in such practice; but, judging from the observations of Dr. Macdonnell, of Montreal, published in connexion with some cases of the kind occurring in his own practice, the treatment is probably worth greater attention than it has had in this country.

CHAPTER VI.

OPERATIONS FOR CLUB-FOOT, BENT KNEE, AND ANCHYLOSIS.

The practice of dividing tendons and other textures, for the removal of deformities, has now become common. Already (p. 314), in the Chapter on Dislocations, I have referred to the division of flexor and extensor tendons in certain kinds of luxations in the toes; but distortions of a more unseemly sort—of the foot, ankle, and knee, may be treated on similar principles.

The method of dividing the tendo Achillis for the cure of club-foot, as first practised by Lorenz, in 1784, under the suggestion of Thilenius, and subsequently by Sartorius, by both of whom free incisions were made through the skin to reach the tendon, has now been superseded by the more simple, more safe, and equally efficient practice of Stromeyer, who has in various ways improved upon the operation as done in 1816 by Delpech. This latter surgeon avoided the free division of the skin, as practised before, but it remained for Stromeyer to point out clearly the advantages of the subcutaneous incision, as well as those principles of after-treatment, which, combined, have given a scientific character to the whole proceedings such as can scarcely be said to have existed before. Since 1831, when Stromeyer first
introduced his operation, his plan of treatment, variously modified according to circumstances and the taste of the surgeon, has been most extensively practised in all parts of the world where surgery is cultivated, and practitioners in England have been much indebted to the labours of Dr. Little (who was himself a patient and pupil of the Erlangen professor), whose treatise on club-foot and analogous distortions has been for many years familiar to the profession.

The most common form of Talipes is either that in which the person rests on the fore part of the metatarsus, whilst the heel is raised an inch or more from the ground, or when the toes and heel are turned inwards and upwards, and the weight of the body is sustained on the outer margin of the foot. The first of these distortions is represented in drawings 239 and 240, being that called talipes equinus, and the second kind (t. varus) is exhibited in figure 244, p. 384. The condition wherein the toes and heel are turned outwards and upwards, whilst the person rests on the inner margin of the foot (t. valgus), is much more rarely met with, unless ordinary flat foot be considered as a mild example.

There are few of these cases in which the division of the tendo Achillis will not greatly facilitate the removal of the deformity; the operation is simple and unattended with danger, and may be resorted to in the earliest infancy or in advanced years with every prospect of advantage. It may be accomplished thus: The patient should be placed on his face, and whilst the heel is bent upwards, the relaxed skin over the tendon should be slightly raised between the finger and thumb, so as to permit the easy passage between the two textures of such a blade as this (fig. 241), flatwise; this being accomplished, the
edge should be turned upon the tendon, which should then be put on the stretch, by bringing the heel downwards, when with a little

Fig. 241.

pressure on the blade the division may be effected. However sharp the cutting edge may be, this part of the operation will be accompanied with a grating sensation, as if it were blunt. As soon as the section is completed, the upper portion of the tendon will recede from the other, and the latter may be drawn considerably downwards, so that a space of from half an inch to an inch may be left between them. If a few fibres remain undivided, and much on the stretch, they should be divided before the knife is withdrawn, or by inserting it again through the little orifice in the skin. Dr. Little and others have recommended that the tendon should be cut from within outwards; i.e. by passing the knife in front of it, and then cutting towards the surface; but the advantage of such a proceeding, as well as whether the blade should be thrust in on the inner or outer margin of the tendon, are matters of no great moment, in my opinion, and may, therefore, be left to the convenience or taste of the operator. Neither do I think the shape and size of the knife of such importance as some seem to imagine, provided always that care be taken to make the external puncture small. I have performed the operation frequently with a common narrow-bladed bistoury, and also with a small scalpel. It will be remarked, however, that in using the edge of these knives a larger wound will be made in the skin than may be wanted, and I have latterly used such a blade as that above represented, which only cuts for about five-eighths of an inch from the point; and the remainder being blunt, and rounded on each side, admits of its being turned in any direction as often as may be required, without further injury to the surface.

In talipes equinus this proceeding will be all that is necessary with the knife; but in other forms of club-foot, the tendons of the tibiales muscles, of the flexor and extensor pollicis, sometimes even of the common flexors and extensors, and also those of the peronei, may require division: in addition, it is often of much consequence to cut across a portion of the plantar aponeurosis by a subcutaneous incision, and occasionally also to divide the short muscles in the sole of the foot, particularly the flexor brevis; indeed, in some instances, when the foot has been very short, and much arched, but when the heel has not been raised from the ground, and the deformity has scarcely amounted to what might be called club-foot, I have seen much benefit result from division of the plantar aponeurosis, and a partial incision of the flexor brevis muscle. There need be no set rules for such operations, nor much hesitation in dividing every texture which seems to offer resistance to the removal of the deformity: in the young
subject the tendons and vessels are all so near to each other, that either of the tibial arteries may occasionally be wounded: I cannot speak positively on this subject; but my impression is, that they are frequently cut across in young children: in my own practice the point of the knife has often been carried so near to one or other of these vessels, that I have felt convinced that one of them must have been divided, in consequence of the flow of blood following the withdrawal of the blade; but I have always found that a little pressure with a pad and bandage has effectually restrained the hemorrhage. In the sole of the foot, too, copious bleeding has been noticed until pressure was applied. Especial care, however, should be taken in operating on the adult, as division of the tibial arteries in such subjects might be attended with trouble. Of course I do not wish it to be understood that no heed should be taken of those vessels in the child; on the contrary, the utmost care should be taken to avoid such important parts; but this cannot always be done, and it may be satisfactory to the young surgeon to know, that if such an event does happen, he need not be in much alarm on that account. It is seldom that danger of any sort accrues from division of tendons for the deformities alluded to. I have occasionally seen partial sloughing of the skin from overzealous pressure, and have heard of one instance of death from over-officiousness with the knife, together with the forcible use of apparatus. A question of amputation was raised, but the patient was in too weak a condition to sanction such a proceeding.

Whatever be the advantage of dividing tendons and other textures (and there can be no doubt it is great), the perfection of the cure depends much upon after-treatment, which consists chiefly of the adaptation of apparatus to restore the foot, in a gradual manner, to its more natural position. Numerous pieces of mechanism have been used and recommended for this object; but for general purposes the foot-board of Stromeyer, or the boot recommended by Scarpa, for the treatment of distortion of the foot, long before these operations on the tendons became so common, will be found of the greatest utility: the former consists of a board, which should extend from the ham to the heel and somewhat lower, having a footpiece which can be moved to any angle or inclination that may be desired, and Scarpa’s machine consists of a kind of shoe with a firm iron sole-plate, having a long rod of the same metal extending from it as high as the knee. Various improvements have been made on the latter by Dr. Little, Mr. Weiss, Mr. Bigg, and others, which, however, need not be described here. Mr. Liston delineated a very simple contrivance for these purposes (Practical Surgery, 3rd edition), and I believe that the splint, described at p. 345 in this volume, might be made to answer in most cases of the kind alluded to above.

The instruments which I most commonly use in cases alluded to, are here depicted. Figure 242 represents that which I deem most appropriate for bringing down the heel in talipes equinus. The slipper is fixed accurately upon the foot by the aid of the lace, and then the two upright bars are brought up nearly parallel with the leg, and held in
that position with the circular band at the top, which fastens round
the leg below the knee. The cross strap below is intended to act on
the instep, and push it into a less elevated position than the extreme
arch which it occupies in such instances. Figure 243 shows the

*Fig. 242.*

*Fig. 243.*

instrument most useful in the talipes varus. When the slipper is
fitted on, the single bar at the outside, when fixed up along the fibula,
brings the sole of the foot downwards and outwards, and when this is
in some degree effected the instrument above delineated may be used
instead, especially when the heel requires some considerable influence
upon it.

With one or other of these machines the foot may be gradually
brought to a more seemly appearance, and to a greater degree of use-
fulness and strength; but much patience and ingenuity will occasion-
ally be required to effect the desired object. I have in some instances
found a common pasteboard or wooden splint placed along the outside
of the leg more effectual, or at all events more manageable in children
than any other apparatus; whilst, on other occasions, I have been
annoyed at the result, after the utmost patience and pains bestowed in
every way.

Figure 244 represents the talipes varus, alluded to at p. 380, and
245 exhibits the same foot, after the successful application of the
knife and other means above referred to. The patient was treated in
King's College Hospital by Mr. Partridge.

It has been a disputed point of practice in these cases, whether the
apparatus should be applied immediately after the use of the knife, or
not until the lapse of some days, or perhaps weeks. I should deem it
improper to force the foot into the wished-for position at the cost of much pain to the patient, or the probable risk of severe laceration and inflammation; but I am of opinion, that the sooner after the incisions attempts to improve the position of the parts are commenced, the more speedily will the cure be effected. In instances of talipes equinus, by the application of force after the division of the tendo Achillis, the heel may be immediately brought into its proper place; but the sudden alteration in all the textures gives much annoyance to the patient, and it therefore seems better to produce the change gradually, although in such a case the extending apparatus should, in my opinion, be applied from the first.

The condition termed Talipes Calcaneus by Dr. Little, in which the foot rests upon the back part of the heel, as represented in this figure (246), is a distortion which, owing to paralysis of the muscles in the back of the leg, admits of little improvement by the surgeon, excepting as regards appearance; but by the division of some of the tendons in front, the tibialis anticus, perhaps, and even the common extensor tendons, the foot may be brought into a more natural condition, as was the case in the instance from which the accompanying drawing was taken.

I have known the tendo Achillis accidentally divided with a cutting instrument; but such an injury is rare compared with the frequent rupture of the part, occasioned doubtless by violent action or re-
RUPTURE OF TENDO ACHILLIS.

istance of the muscles to which it belongs, as in dancing, leaping, moving up a stair, or such like circumstances. When the tendon is divided on the living body for club-foot, the sudden separation is occasionally attended with a slight noise, and when division is the result of rupture from violent action in the calf of the leg, the accident may be accom-
panied with a perceptible snap, and often the sufferer fancies he has been struck or kicked on the part while dancing.

The treatment of this injury consists in keeping the ends of the tendon in contact, which can be done only whilst the foot is held in a state of extension. In order to relax the muscles of the calf as much as possible, the knee should be bent, and by means of bandages, straps, or even a splint, if such be deemed advisable, the limb should be fixed in this favourable position for about three weeks, when the union will be sufficiently strong to permit of partial liberty of movement; it will, however, be many weeks before the patient can use much freedom in walking without the support of a crutch or stick; but ultimately, as I have seen even in very heavy indi-
ciparal, the united parts be-

Fig. 247.

Perhaps the most efficient and easily constructed apparatus for the management of these cases is such as figure 247. A common slipper should have a strap or string attached to the back end of the sole or heel, and this being connected to a band round the thigh will keep the heel up and immovable during the time necessary for the healing of the wound. It may possibly, with such an apparatus, be advisable to place a pad and bandage on the calf of the leg, to keep the upper part of the tendon towards the lower, and at the same time restrain action in the gastrocnemius muscles. The belt between the heel and that round the thigh may be made of leather, as represented in the figure, but if this cannot readily be procured, stout calico or other similar material will answer equally well.

Sometimes a few of the fibres of the gastrocnemius give way, under circumstances similar to those which cause rupture of the tendo Achillis: I have known many examples in persons of a heavy and muscular frame. The lesion is attended with considerable pain, and occasionally with swelling and discoloration from effused blood, which prevent free use of the calf for some weeks after. Rest, with the limb

in a bent position will form the chief feature in the treatment, but
possibly the more frequent, the more recent date
Division of the hamstrings for bent-knee is of more recent date
months, even years, afterwards.

Division of the hamstrings for bent-knee is of more recent date
than the proceedings above referred to. In certain instances, it almost invariably happens that the
power are the result. The practice being attended with benefit where
there was merely sufficing and alteration in the shape of the joint, but not when bony

In certain instances, as a child approaches puberty, the limbs bend
and efficiently applied. In certain instances, as a child approaches puberty, the limbs bend
and efficiently applied.
inwards at the knee, so as to cause that condition termed "knock-knee," and the tendency towards this unseemly deformity may be easily rectified, if taken at an early period, by means of splints and bandages. But if the distortion be considerable and of some years' duration, it may be highly advantageous in commencing treatment to divide some of the contracted tissues. The outer hamstrings most demand attention in regard to this point. I have frequently treated such cases in this way with marked benefit, but have never seen one which so admirably illustrates the judicious interference of the surgeon as an example of the kind related by my friend Mr. Wiblin, of Southampton, in the Medical Times for 15th November, 1851. In this instance the patient, a boy about eleven years of age, was so disabled by the amount of distortion, that he could not use his lower limbs at all, yet, in the course of time, they were made as straight, and in some respects as useful, as if no such deformity had existed.

In examples of bony ankylosis at the knee with the limb greatly bent, it has been proposed by Dr. J. R. Barton, of Philadelphia, to expose the anterior surface of the lower end of the femur by raising a triangular flap, and thereafter to cut out a portion of the bone in a wedge-shape so that the limb may be straightened as the cut surfaces of the bone are approximated. This proceeding has been done with great success by Dr. Barton, and also by Professor Gibson of the same city. In Dr. Barton's case the limb was gradually made straight in the progress of the treatment. At first the gap in the bone was filled with dressing, and during the stages of suppuration and granulation the member was brought into the desired attitude. I do not suppose that such a proceeding has ever been attempted in this country, yet it seems worthy of imitation, for the advantages seem to have been great in both these instances. Dr. Barton's patient could walk with ease at the end of eight months, and could mount his horse with facility, or travel on foot forty or fifty miles in a day.

In recent times, some of the excisions of the knee may be considered to figure under this head. It was in some such cases that I myself advised excision of an ankylosed knee, and such an operation was first performed by my former assistant, the late Mr. C. P. Price, whose work on Excision of the Knee has been brought before the notice of the profession under the editorship of Mr. Henry Smith.

The surgeon has usually every reason to be well satisfied when he succeeds in arresting the fatal progress of hip-disease, by a kind of compromise, as it were, with nature, for a stiff-joint. Some, however, have not rested content with such a condition, and have actually proposed to remedy the ankylosis by cutting through the soft parts, dividing the neck of the femur, and establishing a false joint in this situation. In the absence of any personal experience in such proceedings, I shall only say that I am at a loss to conceive any improvement which such a proceeding could bring about,—such, at all events, as would be equivalent to the pain and hazard of the operation, and were I ever consulted on such a question, I should strongly recommend the
patient to rest satisfied, and be thankful that he had escaped in any way from such an intractable disease.

Dr. Barton has succeeded in one instance in improving the condition of the lower limb by such a proceeding. In this case there was great deformity and loss of power resulting from a fracture in the upper end of the femur, which (occurring in a sailor at sea) had not come under surgical care till the lapse of seven months. A crucial incision was made over the trochanter major, and the surface of the bone having been exposed by raising the four flaps, the saw was applied until the bone was so weakened that it could be snapped across. A somewhat similar proceeding, with modifications which need not be particularized here, has been effected by Dr. J. K. Rogers of New York. In both of these instances the results were highly satisfactory. Mr. Brodhurst and Mr. W. Adams have likewise had cases.

CHAPTER VII.

INCISIONS. EXCISIONS.

Besides the incisions already referred to, many others are required for special purposes. Should a person be web-footed, it is not likely that any interference will be necessary, such as has been described with reference to the fingers (p. 258) when they are congenitally joined together. In civilized life, the person must be fastidious in the extreme who would wish an operation done in such cases. Should, however, anything be desired on the part of the surgeon, he may manage in the manner recommended for the fingers. An additional toe is more rare than a finger, but no special comment is required on such cases.

The surgeon may find it necessary to remove a portion of the nail of the great toe for painful chronic ulceration at its root and margin, onychia—as it is sometimes called. Here, when it is found that the usual ointments and lotions, stuffing small slips of lint between the nail and the ulcerated surface, with the occasional application of lunar caustic, produce no benefit, there should be little hesitation about removing a portion or the whole of the nail, as may be required, and the proceeding may be accomplished thus:—One blade of the scissors (fig. 48, p. 35) should be thrust upwards between the nail and the soft parts as far as the root, and then by closing the handles, the nail is split or cut longitudinally; when, with strong rough-pointed forceps (p. 5), the free end of the part should be seized and by a twist towards the back of the toe its removal will be effected: next, if it is necessary, the other half may be treated in the same manner. If there has been suppuration under the nail, this proceeding is simple, and attended with slight pain in comparison to the case where the horn is still firmly attached by most of its under surface. In the latter instance,
however, it is fortunate that only a small portion of the lateral margin need be interfered with. Under any circumstances there is exquisite suffering for the moment, and therefore the manoeuvre should be speedily accomplished by a firm hold, and a somewhat rude and forcible twist and pull. The whole amount of pain had better be occasioned in an instant than by repeated trials with improper forceps, or an over-lenient use of the hand. The use of chloroform may be said in a manner to supersede these observations as to the pain of such proceedings.

Incisions may be required on any part of the lower extremity for erysipelas; but these need no particular notice here, neither is it necessary, after what has been stated at p. 293, and elsewhere, to refer in a special manner to tumours on the lower extremity, or the operations which may be deemed requisite for their removal. Ganglia are by no means unusual on the dorsum of the foot with those who wear tight boots, and have a high instep: tumours of a similar kind are met with occasionally at the knee, and sometimes in the bursa over the trochanter major. Chronic enlargements of the bursae around the knee-joint seldom require active interference: if, however, absorption be not induced by any ordinary means, the tumours, if thought advisable, may be opened with the knife, or actually dissected away. The bursa in this situation communicate with each other in an extraordinary manner in some instances, and sometimes even with the knee-joint; I therefore advise caution in resorting to the use of cutting instruments, for I have known dangerous inflammation induced thereby within the articulation.

The disease termed "housemaid's knee," is deserving of special notice. This affection is inflammation of a bursa, which is in front of the patella in most individuals, especially in those who from their occupation (as paviors, sailors, housemaids, &c.) subject the parts in this situation to much pressure and friction. The inflammation is usually attended with effusion, first of serum, and then of sero-purulent matter; an abscess is the result, and though in the early stages, the disease may sometimes be arrested by leeches and other means for checking inflammation, it happens much more frequently that treatment similar to that required for abscess is positively necessary, and I shall therefore now refer the reader to the Chapters on Abscess and Sinus in the introductory part of the volume, where he will be at no loss to find the practice which may be recommended in such cases. If an incision be required, as is very generally the case, a single one, about an inch and a half in length, in and directly over the long axis of the patella, should be made; if the matter lies more to one side than the other, a transverse wound may be made in the same direction, so as to expose the interior of the abscess more freely; possibly a crucial incision may be made at once, or it will answer well to make two parallel cuts into the abscess near to each margin of the patella. Sometimes it may seem the best practice to open the collection of fluid wherever the integuments are thinnest; or possibly, in the course of treatment, after having made an opening, another
may be required in a site where the matter is about to burst through
the skin.

Occasionally sarcomatous tumours form over the ligament of the
patella. I have seen and removed many examples of the kind. In all
such a section has presented a hard fibrous aspect. Sometimes growths
have been developed in one side of the bursa,—being merely, as it
were, an increase in thickness; but in most the tumour has been alto-
gether separate and distinct from the bursa, being usually lower down
than that part. Those which I have interfered with have been about
the size of a walnut or billiard ball, and from their size have caused
annoyance.

The bursa over the trochanter major is liable to inflammatory
attacks similar to those in that over the patella, but such cases are
less frequently met with. Sometimes obstinate sinuses in the thigh
result from abscesses of this locality, and occasionally there is caries of
the bone at the trochanter. Some time ago I saw Mr. Partridge dissect
away this bursa, which had become enormously distended with a gra-
nular cauliflower-looking growth from its inner surface.

Tumours of various kinds are met with in the thigh, which may be
judiciously interfered with by the knife. Some of these cases require
much cautious discrimination, and a question often arises as to their
connexion with important parts, and the practicability of removing
them. Generally speaking, those which are deep-seated and firmly
fixed, had best not be interfered with; while those which are super-
ificial and comparatively loosely attached, may, provided all other cir-
cumstances are favourable, be dealt with readily in this way. In the
groin much caution will be required, however loosely the tumour may
be seated. The saphena vein may run over or under the mass in such
a situation as to be in danger from a rash use of the knife, or the
common femoral vein or artery may actually be in jeopardy. I
remember seeing Mr. Syme many years ago remove a very large
tumour from this locality, after a careful dissection, during which the
saphena was much in the way; and more recently I saw my col-
league, Mr. Partridge, remove a growth of nearly similar size from
over the site of the common femoral vessels. In the latter locality, I
consider the hazard of such a proceeding considerable, from the cir-
cumstance that one or more of the branches of the common femoral may
be wounded close to their origin, in which case it may be difficult
to apply a ligature, and the proceeding may not be altogether free of
the immediate danger of tearing open the main artery by some unlucky
use of the forceps or tenaculum. Not long ago I had an instance of
this kind in my own practice, at which I looked with unusual anxiety,
until the ligature had safely separated from a vessel which had been
tied within an eighth of an inch of the common femoral artery, a little
below Poupart's ligament.

Some years ago I assisted the late Mr. Ancell, of Norfolk Crescent,
to remove a fatty tumour from the inside of the thigh in a young
married lady. The growth was not far from the perineum, and being
about the size of a new-born infant's head, it had been the cause of
some alarm to the nurse and medical man in attendance at the lady's first accouchement. In the early stages of labour the nurse had thought it advisable to ascertain how matters were progressing, when to her horror she fancied she felt the child's head on the bed. The doctor, arriving at the time, was told by the nurse that he was all but too late, and so he himself thought at first, until further examination. The child was not born for many hours after. The lady very wisely did not wish another scene of the kind, and therefore came to town to get rid of the tumour at an appropriate period.

Excision of portions of bones may often be practised with great advantage in the lower extremity, whether for caries, necrosis, or exposure resulting from dislocations or fractures.

When there is caries in the toes or metatarsus, there need in general be little hesitation about the propriety of amputation: supposing the distal phalanx of the toe to be sound, if the part behind is removed, the remaining portion, deprived of support, will probably be useless; and when the metatarsal bones are affected, the result will be the same. The best exemplification of this latter remark will be to take the cases of disease of the metatarsal bone of the great toe. The condition of the foot represented by this sketch (fig. 248), is by no means uncommon: the extent of enlargement often excites suspicion, with the inexperienced, that the disease is more extensive than it is in reality. Among numerous instances of the kind which have come under my notice, I have seldom found that any other bone than that which supports the great toe has been affected. Within these few months I have operated on two cases of this description where the swelling was as conspicuous as is shown in the cut, and in both the internal cuneiform and the metatarsal bone of the second toe were sound. Where, then, there is evidence of the disease being limited, the rest of the foot may be saved by the resection of the affected bone. I have already (p. 282) strongly advocated the practice of saving the two phalanges of the thumb, if disease in this part of the hand be limited to the metacarpal bone: here the remainder of the organ may be of much service in future; but in the foot, especially in the great toe, the two phalanges would be of doubtful value; in fact, they have occasioned much annoyance, for it is stated by Dr. Paneast that in an example of the kind which came under his notice, the toe was perfectly loose and useless, and was caused to project nearly upright by the action of the extensor muscles. Experience since the last edition of
this work induces me to say, that even in such an instance as that depicted, the disease is in reality only in the joint, between the metatarsal bone and first phalanx, and that excision may, as I have found in repeated instances, prove a conservative and satisfactory operation.

If two or more of the metatarsal bones be irrecoverably diseased, and if, in addition, in removing them with the corresponding toes, it is also necessary to take away one or more of the tarsal bones, or even portions of them, the propriety of saving the other metatarsal bones may be very doubtful, as the narrow and slender member thus left will prove but an inadequate support to the weight of the body. In such a case I have known the foot to become gradually bent up, so as to resemble the talipes varus, and the patient, from the inconvenience thereby occasioned, and there being no hope of permanent improvement from treatment similar to that pursued in club-foot, was glad to submit to amputation above the ankle.

Some further remarks on these longitudinal amputations, as they have been termed, will be found at p. 418; meantime, I shall pursue the subject of excisions.

In any portion of the tarsus in front of the ankle, there is seldom a favourable opportunity of performing excision: I have frequently attempted to save the foot by laying open sinuses, and cutting away portions of carious bone, but cannot boast of the success of these proceedings, having generally found that the wounds resumed their original condition as sinuses, and on amputation it has been seen that the whole of the caries has either not been removed, or that this disease had subsequently attacked other portions of the bones; moreover, I have invariably found the synovial membrane of most of the articulations in the vicinity so affected, as, whilst it justified the ultimate resource of amputation, showed at the same time the futility of entertaining any sanguine hopes of success from the practice first pursued. Notwithstanding these remarks, I should still deem it right, in many instances, to give this practice a trial before resorting to amputation.

It often happens that the disease is limited to the articulation between the great toe and its metatarsal bone. In such an instance, Professor Pancoast employed resection of the joint. A semilunar flap on the inner side of the joint, dissected backwards, enabled him to expose, isolate, and remove with a saw the head of the metatarsal bone; the end of the phalanx was next removed with the same instrument, and some soft material having been scooped from the interior of the remaining portion, the parts were approximated, and in the course of three weeks healed kindly. During treatment, the extensors inclined to pull the end of the toe upwards, and on that account Dr. Pancoast would in another case be disposed to divide them, as they are of little use afterwards. The shortening was three-fourths of an inch; solid union took place in the site of the operation, and the joint between the two phalanges seemed to serve the part of the articulation which had been removed. Certainly the history of this case gives encouragement to make trial of the practice. No set rules need be given for the performance of the operation. Dr.
EXCISION OF ANKLE-JOINT.

Pancoast judiciously availed himself of the fistulous openings on the inner side of the joint, which he embraced in his semilunar incision; and probably, under any circumstances a flap such as he made may best enable the surgeon to expose and remove the diseased parts. By similar steps I have repeatedly saved the end of the toe, and to all appearance with great advantage.

When the os calcis is the seat of incurable caries, much may be done to save the foot by excisions. If the disease is in or near the articulations with the astragulus or cuboid bone, it is to be feared that the results will differ little from those referred to in the preceding paragraph; but if towards the back part of the bone, its lower, its inner, or its outer aspects, then excision may be performed with every prospect of a favourable termination. Portions of this bone have been removed at all these points, with admirable effect: I have operated very frequently myself, and have had the satisfaction of restoring patients to excellent health, after a few weeks of subsequent treatment, who had been harassed for years by partial disease of this bone. No set rules can be given for these proceedings, as the circumstances of each case may differ from all others. I have usually laid open the skin by a crucial incision of sufficient extent to reach the diseased bone: if possible, I have opened the chief sinus, and removed the diseased textures with the knife, forceps, or gouge, as might be required. On the outer side of the bone, below and behind the malleolus externus, great freedom may be taken with cutting instruments, but on the inner surface care is necessary to avoid the vessels and nerve. Many years ago I had a most interesting case of this kind under treatment. For three years the patient—a man about twenty-six years old—had been disabled with caries of the heel bone. He was unable to put the foot to the ground, and could walk only with the aid of crutches. There was a sinus on the outer and back part of the heel, close upon the insertion of the tendo Achillis leading deep into the bone. Here in removing the diseased portion of bone, I found it requisite to cut across the insertion of this tendon; and so extensive was the caries, that I scooped out with the gouge nearly the whole of the cancellated structure ere I was satisfied that enough had been done. The large cavity, as might have been expected, healed slowly; but ultimately it entirely filled up, and only a slight hollow in the skin was left in the site of the original attachment of the tendo Achillis. The patient could put his foot firmly to the ground, could walk tolerably, and, being free from pain and all other distress usually attendant upon caries, regained his accustomed good health.

The recovery of this patient was highly satisfactory. I was wont to see him for years after engaged in an occupation which required him to be actively on his legs for eight or ten hours a day. After continuing free of illness for more than four years, a chronic inflammation came upon the ankle-joint, when ultimately amputation was performed. A section of the os calcis showed the interior of the bone free of disease, and the large excavation nearly filled with new bone, which differed from the rest of the tissue by being of denser structure.
A hollow remained towards the back part of the bone which was filled with a fibro-cartilaginous substance about the size of a filbert. There was no local indication in any direction that the disease which necessitated the loss of the foot was in any way dependent on the original affection of the heel bone. Doubtless a strong constitutional strumous taint was the principal cause of mischief in both illnesses.

Within the last three years excision of the whole of the os calcis has been performed several times by surgeons of this country. A case of the kind was communicated to the Royal Med. Chirurg. Society by Mr. Page of Carlisle, and is recorded in the transactions for 1850, and another example has recently been brought before the profession by Mr. Gay of the Royal Free Hospital. In both the bone was dissected out from behind, and the rest of the foot was left, with the most satisfactory results. I have not myself met with an instance where it seemed necessary to remove the whole of this bone, but these examples are strongly illustrative of the spirit of conservatism which happily seems to pervade British surgery in the present day.

Mr. Thomas Wakley has even gone a step further in this most praiseworthy direction. He removed both astragalus and os calcis at the same time, with the laudable purpose of saving the rest of the foot, and accomplished the object in the most satisfactory manner. The operation is detailed in the Lancet for July 1, 1848. He removed the os calcis first with a portion of the integument covering it, and then the astragalus with the malleoli, the parts being removed through a gap made in the back of the foot by lateral and posterior incisions. The patient who had undergone this operation was submitted to the notice of the London Medical Society, able to move about on the lame foot with wonderful facility. I have more recently learned from Mr. Wakley that the result was in every way as satisfactory as could be desired.

The practicability, and also the propriety of removing the astragalus, and portions of the bones of the leg at the ankle-joint, have already been noticed (p. 316) in referring to dislocations at this part, and similar proposals have been made for the treatment of disease of the articular surfaces and contiguous textures. Notwithstanding the success attending the two operations of this kind by the Moreaus, the practice does not seem to have had many followers in modern times. I cannot speak from large personal experience in these operations, and I imagine that the cases where such proceedings could be reasonably attempted must be of rare occurrence. Moreau the father, after making convenient incisions through the skin, first cut off the end of the fibula with a chisel, and then sawed across the end of the tibia; he next dislocated the foot inwards, so as to cause the part of the tibia connected with the astragalus to project through the wound, when he dissected it away. His son removed the end of the tibia (for he left that of the fibula) chiefly with the gouge, and in both cases the astragalus was freely cut. Care was taken to preserve the tendons and vessels, and the result appears to have been very satisfactory, particularly in one of the cases, in which it is stated that, although the limb was
shorter than its fellow, and ankylosis followed the incisions, the movements of the astragalus on the neighbouring bones became so much more free than under ordinary circumstances, that the loss of the ankle-joint was almost compensated for. The chief danger in such operations would be division of the principal tendons and tibial arteries, but with due caution doubtless these might be avoided. Under any circumstances, I should consider such operations extremely difficult, and in most instances more dangerous to the patient than amputation at the ankle or in the leg. Were such a proceeding hazarded, the part afterwards should be treated in much the same manner as a compound dislocation.

Excision of the ankle-joint has been successfully performed by Mr. Hancock of the Charing Cross Hospital, and it was the first instance of the kind which, in so far as I know, had occurred in this country. The operation was executed much on the plan pursued by the elder Moreau, as above detailed. The malleoli, with about three-quarters of an inch of the bones above were removed, and the articulating surface of the astragalus was also taken away. The result proved highly pleasing. I have myself repeatedly performed similar operations with excellent results.

These various resections, coupled with the particular kinds of amputation at the ankle-joint, recently introduced by Mr. Syme and by Pirogoff, may be said to be highly characteristic of a leading feature of the surgery of modern times, viz., that of removing otherwise incurable diseases at the smallest possible sacrifice to the rest of the body.

Excisions of portions of the shaft of the tibia are more frequently necessary, or at all events of more frequent occurrence, than those last referred to. In compound fracture the removal of a projecting portion of bone is occasionally of great advantage, particularly if the part be sharp or pointed. I should, however, be cautious about removing the whole or nearly the whole thickness of the bone, especially in the adult, if the fibula is allowed to remain of its usual length: it is doubtful whether in all cases (if, indeed, in any where the entire diameter of the bone is cut across) a sufficiency of callus will be thrown out to unite the remaining portions, and I have known one instance, where this practice was resorted to, occurring about the middle period of life, in which, after the lapse of many months, the ends of the tibia remained united, and amputation was at last resorted to, as the fibula of itself proved an insufficient support for the superincumbent weight.

In disease of the tibia these partial operations are frequently performed, and with much benefit. I have occasionally met with instances of swelling in this bone where I thought it requisite to perforate the shell with a trephine or other cutting instrument, to permit the escape of matter; and collections of pus in or about the periosteum, involving portions of the surface of the bone in caries, are so common in practice that little need be said regarding them here. In some instances, too, ulcers of the skin extend to the osseous
texture, and cannot be cured without removal of the exposed part. Here the carious or necrosed portion of bone may be perceptible to the eye; and, at all events, the probe will immediately indicate the condition of the bone: often, however, the matter makes its way from the interior, through such a narrow orifice, that the probe does not readily pass into it, and unless the surgeon has some suspicion of the nature of the disease, he may actually overlook the presence of extensive caries or necrosis of the cancellated structure. It has often appeared to me, that the value of the cases of this kind related by Mr. Hey, has never been sufficiently appreciated by the generality of practitioners. I have myself met with various instances of the sort, and have experienced the most happy results from pursuing a practice similar to that recommended by this most valuable authority. Many years ago I was consulted by a young gentleman about a small ulcer in the skin over the upper third of the tibia, which had for long resisted all modes of cure. Originally a small abscess had formed in the part; ever since, he had experienced considerable pain in the vicinity, and this, with the continued discharge from the orifice, had at last seriously affected his health. With the probe a portion of carious bone was detected, and I recommended that he should allow me to take the necessary steps for its removal. Accordingly, a crucial incision was made in the skin, and the surface of the tibia was laid bare over the affected part; here a small orifice was found not larger than the point of a probe, which led down to bare bone. I enlarged the orifice with the gouge and forceps, and discovered a portion of the cancellated structure as big as a walnut, dead, emitting a most offensive odour, and loosely enveloped in a tissue similar to that which lines the interior of an abscess in the soft parts. By an additional enlargement of the opening in the outer shell of the bone (which was accomplished with some trouble, owing to its thickened and hardened condition, resulting from new ossific deposit) I was enabled to extract the dead bone. The cavity which was left, gradually filled, and the surrounding swelling at the same time diminished: the surface cicatrized, and some time afterwards I saw this patient with the limb as sound as the other, with only a dimple to point out where the disease had been. I could refer to many similar instances in my own experience, but this may suffice as an example of a practice which, in my opinion may be of much service in averting more serious consequences and abbreviating the tedious character of such diseases.

Mr. Henry Lee published an interesting paper on the subjects above referred to, in the Loudon Journal of Medical Science for January, 1852; and, among the cases related an example of trephining a painful node, with the view of opening an abscess in the centre of the bone. I saw this operation, and was much gratified with its success. On taking out a round button-like portion of the bone three-eighths of an inch in thickness, about a teaspoonful of thick matter escaped, and the patient's sufferings speedily ended. The whole case bore out admirably the valuable views on the nature and treatment of
"chronic abscess of the tibia," inculcated by Sir Benjamin Brodie in his lectures illustrative of various subjects in pathology and surgery.

Large parts of the tibia may be removed, whether the disease be caries or necrosis; but in either case, if the shaft is extensively sacrificed, it may be a question whether, under the circumstances, there is much utility in saving the remaining portion. I have seen one instance in a patient under puberty, where the anterior half of nearly the whole length of the tibia separated by necrosis, without any reproduction of bone; the large openings in the skin cicatrized, but as the person began to move about, and lean on the member, the limb became gradually bent, and was at last so unseemly, and, moreover, so cumbersome, and of so little use, as to induce her to submit to amputation. Possibly, however, the limb had not been sufficiently taken care of in this instance, and the patient had leant upon it at too early a date. Dr. Laurie, of Glasgow, related an instance (London and Edinburgh Monthly Journal of Medical Science, August, 1843), of necrosis of the tibia, occurring in a boy of fifteen, where he removed the whole of the bone excepting the epiphyses, and in ten months a new shaft was regenerated. Nearly two years after the operation Dr. Laurie saw this person, and took the following note:—"The integrity of the tibia is restored by bone as firm, and nearly as large as that of the opposite limb. The leg is very slightly bent outwards a little below the knee. Two sinuous openings still exist, one a little below, and the other a little above the corresponding epiphysis of the tibia, at the bottom of which the probe discovers a small extent of diseased bone. He began to walk on crutches a few weeks after he left the infirmary, and for some months has walked assisted by a staff. He now walks well, with a very slight halt, and is able to undergo a great deal of fatigue."

Further experience has convinced me of the amount of benefit which may be afforded by the removal of portions of the tibia. Some time ago I had a remarkable illustration of this in a patient at King's College Hospital. The tibia was extensively necrosed throughout its shaft, and a thick and dense case of new bone had formed around. By enlarged openings in the new material, and cutting across with forceps the dead portion within at two or three different points, I succeeded in extracting, in many pieces, the whole front of the bone, without interfering with the extremities which were not affected. I had to detach so much of the lower third of the bone, that the remaining part actually broke, and during the after-treatment the fragments were retained in splints. Union took place, and after consolidation and the formation of new bone at various points, a strong leg was the result. Such forceps as are represented in figures 249 and 250 will be found of great service in extracting portions of bone, when firmly impacted in new material. Each instrument is about six or seven inches in length, with strength sufficient to permit of a good deal of energy being displayed by the surgeon's hand.

The head of the fibula was removed by Beclard in 1819, and
portions of the shaft, or the lower end of it, may occasionally be removed with advantage; but cases where practice similar to that above recommended can be put into execution, are of rare occurrence in diseases of this bone. However, a good anatomist, with a correct knowledge of surgical pathology, may sometimes obviate the necessity of sacrificing the limb by amputation, by resorting to some such measures as those referred to, although here it is scarcely possible to state how or under what circumstances these operations should be performed. Many years ago the late Mr. Thomas Elliot, of Carlisle, showed me a portion of the fibula, nearly eight inches in length, which he had successfully cut away for incurable disease. The objections to removing the entire thickness of the tibia stated at page 395 are not applicable here, for the larger one being still left, gives ample support to the weight of the body; and, moreover, be it observed, that should the case be one of necrosis, there is greater probability of reproduction of bone than in instances of fracture, especially if the disease be on a young subject, as it usually is.

Excision of the knee, notwithstanding the frequency of disease in this articulation, and also the success of the operation as first done by Mr. Park, has been, until recently, rarely practised in this country. In early life I had myself seen only one instance, but the condition of the limb, several years after, was very different from that of the sailor on whom the above-named surgeon operated; for here, instead of being able to move freely about without even the aid of a stick, the patient was obliged to support himself by a crutch, whilst the limb hung useless, being shorter than the other by several inches, and totally unfit either for support or progression.

The operation may be performed thus:—An incision between three and four inches long should be made on each side of the joint, over the lateral ligaments, and a third should be carried across the fore part, so as to unite the whole, like the letter H. The lateral incisions should belong more to the thigh than to the leg, and that in front should be
EXCISION OF KNEE-JOINT.

across the patella. This bone should now be detached by dividing the textures around it, close to its margins, and the soft parts should then be dissected upwards and downwards, to a sufficient extent to permit a thorough examination of the joint. To facilitate this, as well as the future stages of the operation, the lateral and crucial ligaments should be divided: the saw, forceps, and gouge, must then be used according to circumstances. The saw should be applied to the point of the condyles immediately above the diseased articular surface, and the forceps (p. 8 and p. 9), will be useful in smoothing points or sharp margins. The diseased portion of the femur, usually limited to the extent of the articular surface, being removed, the head of the tibia should next be severed with the saw from before backwards, as also that of the fibula, should it be involved in the affection. The latter step, however, is but rarely required. In using the knife and saw in the posterior part of the joint, considerable care is required, as there is nothing between the instrument and the popliteal vessels but the posterior ligament and cellular texture.

Instead of the H incision, a single transverse cut across, over the patella, from one lateral ligament to the other, will permit all the subsequent steps being adopted with facility, and for many years I have preferred this line. The patella should invariably be removed whether diseased or healthy. There will be no bleeding of consequence; perhaps not a single artery may require to be tied. The wound should be carefully dressed, the ends of the bones accurately placed in contact, the margins brought together with stitches, and the limb should be steadily supported in the extended position by any convenient apparatus; a Mc'Intyre's splint made straight answers well. The dressing and the after-treatment must be conducted on the ordinary principles of surgery; and if cicatization is complete in the course of three or four weeks, or even as many months, the surgeon may flatter himself that he has done all which his art permits.

Notwithstanding early prejudices, I ventured, in July, 1850, to perform the operation of excision of the knee-joint on the living body. The patient came under my care in King's College Hospital, for the purpose of having amputation performed for painful and protracted disease of the knee-joint of two years' duration. The symptoms were chiefly those of ulceration of the articular cartilages; the knee was but slightly swollen, and the limb retained so much of its healthy appearance that I could not willingly comply with the young man's request. After watching the case for some time and seeing no indication of improvement, I thought of excision being applicable here, as the circumstances seemed to me more favourable for such a proceeding than in most other cases of disease of this joint, which had come under my observation. The operation was accordingly performed in preference to amputation, and the steps followed were almost precisely such as are detailed in the preceding page. As regarded mere execution, and also the condition and position of the parts immediately afterwards, everything was most satisfactory. But violent inflammatory fever speedily set in, causing more than usual constitutional dis-
turbance, and death occurred on the ninth day from the operation. One of the most distressing conditions after the operation, was frequent starting in the thigh and grating of the bones. Before death, there was some slight suppurative in the wound. Many of the symptoms induced me to suspect phlebitis, but on examination after death it was found that the principal mischief was in the lower part of the femur, which, for about four inches from the wound, was divested of periosteum, and had its cancellated tissue infiltrated with lymph and pus.

The body everywhere else was in a healthy state.

This result proved most unfortunate for the character of the operation, and must be taken with other cases, as proof of the hazard of such a proceeding. A case in many respects similar has been related by Mr. Syme as having occurred to him; but after all it may be questioned if it be fair to attribute the results solely to excision. Acute necrosis of the femur is a well-known result of amputation in the thigh, and my own impression is that had amputation been performed in these very cases, the same results might have followed.

Since the early editions of this work were published, the history of this operation has been peculiarly eventful. In January, 1851, six months after the operation which I performed in King’s College Hospital, it was repeated by Mr. Jones, of Jersey, and the result was highly satisfactory. In little more than twelve months this gentleman performed the operation in three other instances, and three of these four were followed by the most pleasing results. Then Mr. Page, of Carlisle, adopted it with equal effect. Again it was performed by Mr. Jones, and again by myself, when the late Dr. Mackenzie, of Edinburgh, performed it in the Royal Infirmary of that city. Next, Dr. Pritchard, of Hunmanby, tried it, then Mr. E. Thomas, of Manchester, and again it was performed by myself in King's College Hospital. An able memoir soon appeared from the pen of Dr. Mackenzie, which was speedily followed by one of equal merit from Mr. Henry Smith, who had also successfully performed the operation. A paper was then presented to the Royal Medico-Chirurgical Society by Mr. Jones, detailing remarkable success in the operation, when, in 1855, there was published in the Dublin Quarterly Journal of Medical Science (by Mr. Butcher, of that city), a more compendious account than any yet given on this subject. Many additional notices appeared in the Medical Journals, among which I may particularly notice those of Mr. Henry Smith and the late Mr. Price, to both of whom I have often been greatly obliged for assistance in those operations; a second paper appeared in the Dublin Journal above-named for July, 1857, by Mr. Butcher, in which he gave the particulars of upwards of eighty cases, and showed that the success of these operations had been far above the average of ordinary amputations in the thigh.

But the most remarkable of all yet written on the subject was an essay by Mr. Price, who brought together more historical and original truths than had yet been presented to the profession. Mr. Price had enjoyed peculiar advantages in studying the subject, of which he availed himself to the utmost, and was among the first to bring Photo-
EXCISION OF KNEE-JOINT.

401

graphy to bear on the subject; many of his cases and facts in pathology were equally original, and no such monograph had yet been offered to the profession. Bad health and death arrested the labours of one who had given the highest indications of a brilliant future career; but happily his Essay has been preserved and presented to the profession in a goodly volume, edited by his attached friend, Mr. Henry Smith, who took the opportunity of posting the subject up to the date of publication.* It is illustrative of the eagerness which the profession has evinced on this subject, that soon after Mr. Price's death, another Essay was set about by Mr. William P. Swain, of Devonport, which in due time secured to its author the Jacksonian prize (1865) of the Royal College of Surgeons of England. The Essay, further elaborated, has since been published in the pages of the British Medical Journal and in a separate form,† and contains the greatest amount of information on the subject that has yet appeared. The circumstance that Mr. Swain was house-surgeon at King's College Hospital and a zealous pupil of my own, has filled me with especial interest in his labours in this department of what I may call Modern Surgery. In addition to these references, I may allude to a variety of publications of my own on the subject, and particularly to two Lectures‡ which were delivered at the College of Surgeons in June, 1864, when I was Professor of Human Anatomy and Surgery in that institution, wherein certain points of interest were specially referred to—such as dealing with the epiphyses, with reference to the subsequent growth of the limb in young persons, cutting out ankyloses to improve distortion, repeating the operation when the healing process had not followed a first or second—points which were at that time of peculiar interest owing to the writings of Mr. Pemberton, Dr. Humphry, Dr. Keith, and others, all eagerly engaged in this field of surgery.

From 1781, when the operation was first performed by Park, up to 1830, it had been done nineteen times in all, and seven of these were effected by British surgeons. In these islands it was all but forgotten for twenty years. Notwithstanding the unfortunate result in my own first case of its revival, the character of the operation, coupled with the success of the cases of Mr. Jones, as related by Mackenzie and others, seemed so much in accordance with the modern practice of surgery in this department, that it was speedily repeated by many of the leading surgeons in Great Britain. I know of no new operation, as it may yet be called, in the whole range of surgery, which has been so frequently performed in such a brief period since its revival, and I have confidence in stating that I know of none so thoroughly worthy of the attention of the surgeon. Amputation has often been called the opprobrium of surgery. Modern practice has done much to set this axiom aside. It is difficult to say whether pity, amazement, or horror is uppermost in the mind when one hears, now-a-days, of amputation in the arm for disease of the elbow-joint, and such I believe will be

the case in a few years hence when some "statistical table" shows how
a patient has fared after amputation in the thigh for "disease of the
knee-joint." That such a proceeding is never needful in such disease
I am not prepared to say, but I firmly believe that in eight persons
out of ten, under the age of twenty or thirty, in whom disease of the
articular surfaces of the bones of the knee-joint seems incurable, the
operation of excision should be preferred to that of amputation.

The wound is less than that in amputation in the thigh, the bleeding
seldom requires more than one or two ligatures, the loss of sub-
stance is less, and probably on that account there is less shock to the
system, the chances of secondary hemorrhage are scarcely worth
notice, as the main artery is left untouched; there is, in short, nothing
in the after-consequences more likely to endanger the patient's safety
than after amputation, whilst the prospect of retaining a useful and sub-
stantial limb should encourage both patient and surgeon to this practice.

One of the strongest objections to this operation has been the
length of time needful for a cure. Some patients have been twelve
and eighteen months under treatment, whilst during the period some
who have had amputation performed have been declared cured. But
the objection I believe is fallacious, and made without experience or
data. I have had a patient on crutches within six weeks after resec-
tion; I have rarely seen one about at an earlier period after ampu-
tation; and I have seen one walking firmly and nimbly within twelve
months after resection, in a style far superior to that which an unfor-
tunate might display with an artificial limb. My impression is, that
as we improve on the after-treatment of these cases, the result will be
even more satisfactory than that already achieved.

The after-treatment I consider of great importance. Generally it
may be said to resemble that which is needful in compound fracture—
the nicest and closest possible approximation of surfaces, the utmost
steadiness of all the parts, the suppression, if possible, of all undue in-
flammation, the free escape for discharges, are all points of importance
here as in fracture. In King's College Hospital we have almost in-
variably used Salter's swing (already referred to at p. 347 as peculiarly
advantageous in fractures of the leg), and I strongly recommend it in
all such cases. Some additions have been made for these special
instances by subsequent house surgeons, particularly by Mr. Lawson
and Mr. Parkinson. The limb is generally laid in such a splint as is
here represented (fig. 251). With good padding it lies comfortably

Fig. 251.
upon it, and the side splint assists greatly in keeping all steady, whilst, from its construction, it admits of ready ingress to the wound.

Figure 252 gives an accurate representation of a limb about twelve months after resection of the knee. The lad on whom the operation was performed could walk easily ten or fifteen miles a day without trouble or distress of any kind. There was a firm ankylosis at an early period, and, as may be observed on the sketch, the shape of the part is so little altered, that were it not for the ankylosis and shortening of the limb, as well as the known history of the case, one might hesitate about believing that such an operation had been performed. The patient still lives, an active, vigorous man, and has gained some renown as a good cricketer.

Operations with cutting instruments are rarely required on the shaft of the femur; indeed, unless on the trochanter major, I am not aware of any operation for cancers having been done on this bone, with the exception of those that have been performed at its articular extremities. I have treated many instances of cancers and necrosis on or in the trochanter major by the gouge and saw most satisfactorily, and have seen others where such practice might have been of service. Longitudinal and crucial incisions through the soft parts have sufficed to make the requisite space for these instruments being efficiently applied. Abscesses occasionally form in the large bursa between this prominence of bone and the tendon of the gluteus maximus, and in some of these cases ulceration and cancers come on. To effect the removal of disease in this process, a free crucial incision should be made through the skin and tendon of the gluteus maximus, and when the surface is sufficiently exposed, the gouge should be used to scoop the affected parts away. I should myself place most reliance on this instrument; but, if the disease proved extensive, should be inclined to divide the attachments of the glutei to the upper and fore part of the process, and then effect the removal of the entire trochanter by the united aid of saw and forceps. A small Hey's saw would be more manageable here than any other.
In some instances of necrosis of the femur, the surgeon may effect much by judicious interference, although, unfortunately, considering the frequency of the disease in the shaft of this bone, the cases are but few in number where any attempt should be made to remove the dead part. I have seen a large portion of the shaft taken away through an opening in the front of the thigh; but in that instance, the plan of treatment was very clearly indicated: two inches of the necrosed portion of bone projected through an ulcer in the soft textures, and, nature having already nearly completed the separation, the surgeon had only to take hold of the sequestrum with his fingers and apply a little force to pull it out, at the same time touching with the edge of the knife such of the soft parts as seemed to offer any resistance. But it seldom happens that the dead portion is thus thrown out of the axis of the limb, and in general before it is loose it has become so enveloped with new bone that the surgeon sees no way to interfere by a local operation. Of many cases of this kind which have come under my notice, there has seldom been any choice beyond amputation, or lingering illness; and among the instances where I have succeeded in removing any portion of bone, the following is one of the most remarkable. A boy, aged sixteen, had suffered for two years from necrosis of the lower third of the femur: when he first came under my care the whole shaft was thickened, and the new bone seemed most developed at the lower end, just above the condyles, where, through several openings of the skin, a large dead portion could be felt with the probe. Perceiving that this sequestrum was surrounded by a thick case of new structure, little hope was entertained of saving the limb; yet, to ascertain the possibility of extraction, I laid open one of the sinuses situated on the outer margin of the tendon of the biceps and exposed one of the apertures in the new bone; next the edges of this opening were pared with the gouge and forceps, and having with these means taken as much liberty with the new bone as was deemed justifiable, I attempted to pull away the sequestrum with a pair of strong forceps, but not succeeding, gave up the attempt in despair. A month after, the boy's health having in the interval improved considerably, I again resolved to try extraction, and on this occasion used the cutting instruments still more freely, when after much labour (for such a term is truly applicable to some of these operations), I succeeded in extracting a portion of dead bone about four inches in length, comprising the whole thickness of the original shaft: several smaller portions had been previously cut off with the forceps, to permit the more ready removal of the main part: indeed, it was my intention on this occasion to have cut the sequestrum into pieces, had I not succeeded in removing it entire, and thus have been enabled to extract it bit by bit. The discharge from the large cavity soon assumed a healthy appearance, the callus in the course of three weeks had already diminished in circumference, all pain in the limb had ceased, the gap was gradually filling up, and the patient returned to the country with every prospect of a complete cure. Since these remarks were first written I have had many similar cases both
in the young and long after puberty, and the results have been thoroughly satisfactory.

Mr. Jones, of Jersey, has published two cases, in each of which he removed fully three inches of the entire thickness of the femur, close by the trochanters, in various and numerous portions, resulting from fracture. In both instances osseous union occurred, and although the limbs were shortened to the extent of bone removed, they proved very serviceable.

Excision of the head of the femur prior to 1842 had been performed about a dozen times, and one half the number survived; but experience as to the results of this operation was then so limited, that, in the first edition of this work, I could scarcely say more on the subject than express a belief that, in some instances of disease and of gun-shot injury of the neck or head of the bone, such a proceeding might be of service. If the operation were undertaken for disease of the hip-joint, it would probably be necessary in most instances to scoop away portions of the cotyloid cavity at the same time; but as in such cases the extent of disease in the os innominatum could not well be ascertained before making incisions, and possibly not even then, I feared that the results of the operation would often cause disappointment. Although for more than ten years I meditated the performance of this operation in morbus coxarius, I never, amongst the numerous cases of this kind which come under my notice, met with a single instance where the practice was deemed justifiable. The fatal character of this disease after caries has been established is but too well known; yet the case is not always without hope, and practitioners of much experience must occasionally have witnessed remarkable recoveries contrary to every reasonable expectation: such instances I have myself seen, and in others, when death has occurred, I have generally observed that the disease has covered a surface so extensive, and that the surrounding textures have at the same time been so involved, that an operation would have been utterly fruitless. In gun-shot injury the operation has been proposed to save the patient from almost certain death, or the fearful and precarious alternative of amputation at the joint, and in future wars the recommendations of such high authorities as Mr. Guthrie, Sir George Ballingall, and others of almost equal note, may possibly be put to the test of experience. In 1832, Mr. Suetin performed this operation at the siege of Antwerp; fifteen splinters and six inches of the bone were removed, but the patient died from gangrene on the fourth day.

The head of the bone may be turned out of the acetabulum in the following manner:—The body being placed a little to one side so as to elevate the hip, an incision with a strong bistoury should be carried in a semilunar course about two or three inches above the trochanter, its ends being so limited as not to interfere with the crural nerve in front, or the gluteal artery behind: from the centre of the concavity thus formed, a straight line of incision should be carried downwards over the trochanter, the two being each of a length proportioned to the bulk and depth of the parts. The knife should be carried deep,
and one flap should be turned forwards and another backwards, so as to expose the upper part of the trochanter, neck of the bone, and capsular ligament—the three glutei, especially the medius and minimus, being freely cut for the purpose. The capsule should next be opened on its upper and outer aspect, when by twisting the thigh across its fellow, and rotating it outwards at the same time, the head of the bone will start from its socket: if the round ligament remains entire, which it probably will unless considerable force is used, it can be touched with the knife, and the articular surface of the femur will now be thoroughly exposed. The saw may next be applied to the neck of the bone, and the head being separated, the chief steps of the operation will be completed. In gun-shot fracture, the lever force of the shaft of the bone will be wanting; but Sir George Ballingall seems to think this of little consequence; and in disease of the joint there may be circumstances demanding modification,—as, for example, the head of the bone may already be dislocated, and in great part absorbed; but formidable though the operation be,—and I should consider it extremely so,—the difficulty of performing it would not, in my opinion, be equal to that attending the selection of cases in which its application would be reasonable. Hemorrhage from branches of the gluteal artery would, probably, be considerable, and it is evident that if the incisions were carried too far in front or behind, irreparable injury might be inflicted on nerves as well as vessels.

Not long after these remarks were written I met with an instance of morbus coxarius, where there was almost every inducement to perform excision of the head of the femur. The patient, a boy of fifteen years of age, was in the last stage of hectic, having suffered acutely for above twelve months from this disease, which had run its various stages until the head of the femur had been luxated on the dorsum ilii, where it could be felt beneath the skin among such portions (if any) of the glutei muscles as had been left entire. There was an open sore over the trochanter major, leading to a large and deep sinus, through which the finger could be placed on the head of the bone. The condition of the hip is tolerably displayed in this drawing (253), but the

**Fig. 253.**
distortion of the limb is not so apparent as it was on the patient, while the artist has taken the liberty of causing the muscles of the thigh and leg to appear in a much more vigorous condition than they were in reality. The knee on the affected side rested about the middle of the thigh of the sound limb: the obliquity of the pelvis was great, as was also the corresponding curve in the loins. An incision through the skin and other tissues indicated by the line on the drawing, enabled me to expose the portion of the femur which I had resolved to remove: the head, neck, and trochanter major were isolated and thoroughly turned out of the wound by twisting the limb over the opposite thigh, and a common saw enabled me to effect the separation of four inches and a quarter of the femur. Before exerting the head of the bone, I made an awkward and unsuccessful attempt to effect the section of the shaft below the trochanter with a chain saw, but should I ever perform a similar operation again, the common saw (p. 7) will content me. Scarcely an ounce of blood was lost, no vessel required ligature, there was little or no shock or constitutional disturbance in the form of symptomatic fever, great part of the wound healed by the first intention, the hectic disappeared, and now six months having elapsed, the boy is in excellent health and without complaint. There are still two small sinuses in the line of the cicatrix, but they are gradually getting less, and there are no indications of remaining disease either in the pelvis or femur. The upper end of the shaft of the bone rests in the site of the acetabulum, and a kind of fibrous false joint will in all probability be the result. The limb is about two inches and a half shorter than its fellow, and the difference in this respect with reference to the length of the bone is that the latter was measured by the curve in the neck. I was encouraged to perform this operation by the success which had followed the practice of the late Mr. Anthony White of the Westminster Hospital, who, in the year 1818, operated in an instance to which the above case bears a remarkable similarity, both as regards the condition of the disease and the operation. Mr. White's case was the first of the kind in Britain, my own, I believe, is the second, where success has followed. The incision through the surface is such as was originally recommended by Mr. Charles White, of Manchester, in 1769 (who was the first to propose this operation, though there is no proof that he ever performed it on the living body), and from my experience in the case above referred to, as well as from experiments performed on the dead subject, I am inclined to think that there is no necessity for the extensive use of the knife recommended at p. 405; for, even in the event of more room being required than a single incision of moderate length will afford, a transverse wound through the tissues in the vicinity of the trochanter major (as was made by Suetin) will permit exposure of the parts in the vicinity of the articulation.

Like resection of the head of the humerus, many different methods of exposing the upper end of the femur have been recommended by Roux, Velpeau, Jäger, and others, which, however, I shall not describe, for here, as with the shoulder, I hold the opinion that a knowledge of
anatomy will best enable the surgeon to suit the proceeding to the peculiar features of each case. It would be folly to make a larger wound than is required for the due performance of the operation, and so long as the operator limits himself,—in front, so as not to meddle with the branches of the crural nerve, or endanger the femoral artery; and behind, so as to protect the sacro-sciatic nerve,—it seems to me of little consequence what lines are cut on the surface. A straight one will, I believe, answer in general, but, with the views above inculcated, it matters not what shape the flaps may be. I imagine that there is little to be dreaded from hemorrhage: the only arteries of magnitude in the way are the gluteal or some of its branches. The latter will not bleed copiously, and there is little risk of coming in contact with the trunk itself.

The after-treatment, in my case, consisted chiefly in water-dressings, quietude, and the use of a splint. The latter was applied with the threefold object of keeping the parts steady, securing a certain amount of extending force, and straightening the limb at the same time. The apparatus used was such that, while it answered these different objects, it also permitted the dressings being applied with the smallest possible amount of annoyance to the patient, or trouble to the dresser. Figure 254 shows the lower part of the body with the splint adjusted, and it

Fig. 254.

will be observed that the extending force is taken from the opposite limb—a mode of proceeding differing from that which has been alluded to at p. 359, in my observations on the treatment of fracture of the neck of the femur. In such a case as this, if extension, by means of a perineal band, had been kept up in the ordinary mode with the long side splint, the soft parts in the upper end of the thigh near the fork, would, in all probability, have been drawn in the direction of the acetabulum and prevented that close approximation of the bones which was desired, but by taking the fulcrum from the other side there was no such chance. The extending force was intended to be just sufficient to prevent the upper end of the femur from projecting through the wound or riding on the dorsum ilii, and the bandage round the lower part of the thigh and upper part of the leg, was applied to assist in straightening the knee—a process which, both here and in the spine, was expected to go on favourably under the altered position and circumstances of the patient. The thigh-plate of this splint, being moveable at will, was taken off at
each dressing, and thus the wound could be reached with a facility which no other apparatus — possessing all the advantages above referred to—could have admitted. Other particulars regarding this case will be found in the volume of "The Transactions of the Medico-Chirurgical Society" for 1845.

Since the third edition of this work was prepared, in 1846, I have had further experience regarding the operation above particularly referred to, and the subject has been occasionally brought under the notice of the profession in various ways. My former pupil, Mr. Henry Smith, devoted especial attention to it; Mr. H. Walton also wrote on the subject after some personal experience, and my esteemed preceptor in anatomy, Dr. Knox, recorded his views upon it in an interesting paper published in the Medical Times for 28th June, 1851.

Besides the operation above detailed, I have resorted to a similar proceeding in three other cases of morbus eoexarius, under circumstances in most respects essentially similar. One of these patients died about two years after the operation of enlargement of the liver, after having experienced great relief from the proceeding. The wound never entirely healed, and on examination after death a small portion of necrosed bone was found loose in the acetabulum, no doubt a portion of the margin of the acetabulum which had died subsequent to the operation. Here I thought it advisable to elip away the circumference of this cavity, in consequence of earies, and possibly may not have removed the whole of the affected bone. The remaining portion of the cavity was now healthy. Unfortunately, in this instance, the second on which I operated, I left the trochanters, being under the impression that by taking away the diseased head of the femur only, I lessened the danger, but it was found in the after-treatment that the trochanter major so projected outwards in the line of incision as greatly to retard the closing of the wound, and I had no doubt, on inspection after death, that it had acted as a kind of cap to the acetabulum, and prevented the necrosed portion of bone, above referred to, from getting out. The other three cases are alive and in the enjoyment of excellent health. The boy, first operated on in 1845, is now, after the lapse of more than seven years, a stout, able-bodied young man. A false or new joint has formed in the eicatrix, and he can move the limb as nimbly as the other, although not with such force. It is now nearly six inches shorter than its fellow, but with the aid of a high-heeled shoe and a stick the young man can walk ten miles at a time without either trouble or fatigue. The case originally operated on by Mr. Anthony White, in 1818, died of disease of the lungs about five years afterwards, and the parts concerned were secured and placed by Mr. White in the Museum of the Royal College of Surgeons. The eotyloid cavity has in a manner disappeared, and in its place there is a stout fibrous tissue, which binds the femur and innominate strongly together, but yet permits of tolerably free movement. I have little doubt that the parts are in a very similar condition in the case of my own above referred to. Happily, so far as can be judged at present,
there is no likelihood of any early opportunity of anatomical examination being permitted.

In one case (a girl about nineteen years of age), where there had been long-continued suffering from morbus coxæ, I commenced an operation with the intention of removing the head of the femur, but found it firmly attached to the cotyloid cavity by ankylosis, and that the succession of large abscesses at the hip and upper part of the thigh, which characterized this case, arose in all probability from a portion of carious bone at the upper and back part of the neck of the femur, close to the trochanter major. By removing this process I got readily at the affected portion of bone, and finding no other trace of disease, excepting that which had passed away, I was in hope that success would follow this excision of the trochanter and small portion of the neck of the bone, but unfortunately severe erysipelas set in and carried off the patient within a week. This is one of the cases referred to at p. 327, and I mention it here because, when I began the operation, I expected to find the head of the femur partially luxated and in such a state as to warrant its removal. Here, however, I had been in error, and I have often since, in examining distortion from morbus coxæ, had reason to consider it a very difficult matter to be altogether sure when the head of the femur is luxated in such cases. In many of the instances where this is supposed to be the case, I believe the shortening of the limb with the prominence of the trochanter, as well as its seeming proximity to the crest of the ilium, are owing to a change in the line of the neck of the femur. I allude to these changes irrespective of the curvature of the spine, obliquity of the pelvis, and also of the limb,—all of which with other circumstances, contribute to the distortion of the hip which resembles luxation, chiefly with the view of giving caution to the young surgeon not to decide rashly upon such a question. I am disposed to say, after my own experience on this subject, that when the head of the femur is in reality out of the acetabulum, the indications are usually so distinct that there is hardly room for doubt, and I may add, that when there is doubt, in all probability the suspected luxation has not occurred.

Besides the cases of resection of the upper end of the femur, which I have myself had, I have seen it done in three other examples. Once by Mr. Henry Smith, the particulars of which are published in the Lancet, vol. i. 1848, and twice by Mr. French, surgeon to the St. James's Infirmary. Mr. Smith's patient was thirty-three years of age, had a short relief from pain, although he never was able to leave his bed. Great part of the wound closed, but the discharge continued in more copious quantity than could have been anticipated. On his death, four months after, a long sinus extended in the line of the psoæ muscles up to the spine, where there was slight caries, and there was every reason to suppose that a lumbar abscess had been present for some years before the patient was laid up with the disease of the hip. Some gentlemen of large experience, who had examined this case before the operation, had entirely overlooked this condition, and, for my own part, having also been consulted about it, I had no suspicion
that such a complication was present. In both of Mr. French's cases, girls under puberty, the exhaustion, from long-continued disease, was extreme, yet the recovery in each case was most satisfactory.

Various other cases have been operated on in London, but with indifferent results. Several examples have occurred in the country, and two have been published. One by Mr. Cotton of Lynn, which was unsuccessful, the other by my friend, Mr. Morris of Spalding, from whom I have recently had the most satisfactory accounts of his patient.

It would not be in accordance with the arrangement of this work were I to dwell longer on this subject. My opinion as to the propriety of this operation in certain cases, has not in any way altered since I first read the interesting history of Mr. Anthony White's case. The experience of twenty-five years leads me to think that such cases must be rare, although I have no doubt that the proceeding might have been much more frequently resorted to, and most advantageously, had surgeons acted on the brilliant example given them by Mr. White, whose boldness of conception and cautious judgment, combined with much reliance on the powers of nature, were well known and appreciated by those who were familiar with his professional career.

I prefer, even in this edition, to allow the remarks and descriptions as above to stand without any special correction or change, because they shadow out the history of the operations and my own views on the subject. Nearly forty years after it was suggested by one of the most original thinkers among English surgeons, Mr. Charles White, of Manchester, it was left for Mr. Anthony White, of London, to show that in certain instances it might be satisfactorily and successfully performed. Notwithstanding the brilliant result of that proceeding, twenty-seven years elapsed ere a similar attempt was made. Since 1845, however, the operation, as revived by myself, has been frequently repeated, and with such success as to induce me to give it my strongest recommendation. Cases wherein it is advisable are rare in comparison with those of disease of the knee or elbow; but I believe they are more common than of the shoulder. Disease of the shoulder-joint rarely destroys life; that of the hip-joint frequently does so. In spontaneous recovery at the shoulder, there is less deformity and more comparative utility than in a similar result after morbus coxarius.

Although I believe that even at the shoulder resection may possibly save life, I am of opinion that such a proceeding at the hip may be eminently successful in this way. In Mr. White's instance the patient lived years after, and enjoyed excellent health. In my own case the patient yet lives, has never had a serious illness for twenty-four years, and can walk fifteen or twenty miles a day with perfect ease. There is a false joint at the hip, and although the limb is short by six or eight inches, he can move about with the utmost facility. Since 1845 a start has been given, and I have now no hesitation in stating my opinion that, in properly selected cases, this operation will prove eminently successful in saving life. One of the main objections to the proceeding has been the probability of disease being in the cotyloid cavity as well as on the head of the femur. The same argument might
be brought against resection at the shoulder, but at this joint it is supposed that the surgeon may be able, if needful, to cut away disease from the glenoid cavity. It has never been thought an impracticable or even a difficult thing to remove the glenoid cavity should such seem necessary, but curiously, without practical knowledge on the subject, it has been supposed impossible so to manipulate with the acetabulum. No greater mistake can be imagined, for if the trochanter major be taken away—a step which I recommend should always be effected—it is actually easier to get at the acetabulum than at the glenoid cavity. The curved forceps and gouge (figs. 14 and 17, p. 9), will enable the operator to remove as much as may seem needful. Bleeding has also been considered an objection to this operation, but if properly done there will be less than at the shoulder, and even a single ligature need not be required. The wound is little in comparison with the magnitude of the disease, and I firmly believe that more frequent performance of this operation would greatly alleviate human suffering and enhance the character of surgery. In further exposition of my own views on this subject, I beg to refer to the Lancet and Medical Times for 7th April, 1849, wherein a clinical lecture of mine was published; and among those who have strongly advocated this proceeding, after personal experience, I may name my friend Mr. Hancock, of the Charing Cross Hospital, who has published an elaborate paper on the question in the first volume of the Lancet for 1857.

It has been supposed by many that this operation is peculiarly eligible in military practice, but the experience of recent warfare in the Crimea has only produced one instance. In a case of bullet-wound of the trochanter major and neck of the femur, Mr. O'Leary, surgeon, 68th Light Infantry, performed this operation on a young soldier, who made an excellent recovery, and was seen in London some time afterwards in excellent health. The case was published in the 2nd volume of the Lancet for 1856.

Few things, in this new edition of a work of nearly thirty years' continuous good reputation, give me greater satisfaction than to refer to the progress of this operation in both civil and military practice. As a civilian, I can testify to its continued rational success. In my own practice it has gratified beyond expectation. In examples of hip disease, like those met with in former years, when all appeared hopeless, a new tenure of life seems to have been imparted by its performance; and no better proof can be indicated of the value of the doctrines and practice of "the Whites," of which I became the humble exponent in England—than this, that in 1870 a paper of Mr. Gant's, of the Royal Free Hospital, read at the Medico-Chirurgical Society, elicited a prolonged and adjourned discussion on the subject, which brought out opinions in general approval, from nearly a score of the best young Hospital Surgeons in London of the day.

Modern surgery certainly owes much to our American brethren, and in few respects more than in regard to this grand topic. I have the greatest satisfaction in referring to "A Report on Excisions of the Head of the Femur for Gunshot Injury, 1869," by Surgeon and
FALSE JOINTS. 413

Lieutenant-Colonel George A. Otis, U.S. Army. Here the most comprehensive history of the whole subject yet published has been put together. It redounds to the credit of surgery, yet for the sake of humanity, it may be hoped that such a mass of experiences within a brief period, may never again fall to the lot of a single generation. I perceive that in this Report the name of my former friend, Sir George Ballingall, is used among others as a worthy authority; but I little thought, some forty years ago, as I demonstrated to that gentleman the easy practicability of excising the head of the femur on the dead subject, that I should be the modern pioneer (in this country) of resuscitation of the proceeding in civil practice, and so, as I hope, have given encouragement to that "Conservatism" which has been so signally displayed in the practice of American surgeons in the United States Army, and also among their gallant contemporaries in the Confederate service.

False joints in the lower extremity are of a more serious character than those of the pectoral, as they interfere with the powers of progression, and if not remedied produce permanent lameness. In the superior extremity this defect is of most inconvenience when in the humerus; and the same may be said of the lower limb when it is in the femur. There is one exception, however, to this general remark, and that is the instance of false joint at the neck of the thigh bone, within the capsular ligament, which, when tolerably perfect, gives a fair result to this fracture. The long bones of this extremity are occasionally broken during delivery, and there is a possibility of false joint being the result. This, perhaps, is not much to be wondered at, considering the frequent movements of an infant's limbs, but whether these movements be in reality the cause of non-union in such cases need not be discussed here. Perhaps the accident is most frequently overlooked in the bones of the leg. For my own part I do not remember to have seen a case of fracture in the femur in an infant, which had been so long overlooked that a false joint had formed, but I have seen many instances of the kind in the leg. These have been discovered only at the time that the child has begun to put its feet to the ground. I once watched a case of this sort for many years. The boy was between six and eight years old when he first came under my notice. He then walked lame, the injured limb being shorter than the other. The false joint was in the lower third of the leg. As he stood upon the unsound part the upper fragment could be observed slipping over the under one, and it seemed surprising that it did not burst through the skin. The boy, notwithstanding, moved about with wonderful facility, and joined in the games of his companions. As he grew older, however, the weight of his frame caused the tissues around the false joint to yield, and partly by overlapping and partly by bending, the limb became so short and so troublesome that, about the age of thirteen, he had the part amputated by Professor Lizar. There is a moist preparation in the Museum of King's College, which gives a fair resemblance to the joint as seen in that instance after the leg was dissected. Here is a representation of the parts to which I
refer (fig. 255). The bones are from a younger person than Mr. Lizars' patient was when amputation was performed. The round end of one fragment, the cup-like shape of the end of the other, and the new capsule, give a good representation of a false joint, which had probably existed from birth, and which had begun to yield to the weight of the body as the child had grown. I do not know the history of this case. There is no evidence of anything having been attempted, and probably amputation had been resorted to at an early period. In the case treated by Mr. Lizars, no attempt was made to induce a junction of the fragments. Years ago I watched for eighteen months, and in part treated, a case similar to the two above named. The patient was a healthy-looking girl, about four years of age, and nothing was known as to when or how the fracture occurred. In all probability it happened during birth. It was only discovered at the time when she was about getting on her feet.

When I saw her first she was two years old, and already there was considerable projection forwards at the seat of mischief. By means of apparatus the limb was, under the judicious care of Mr. Pyne, of Royston, put straight, and then I tried the plan of subcutaneous incision, recommended by Professor Miller, of Edinburgh. No good effect followed, however, and the leg was merely kept in a straight position with an instrument which, in some degree, took off the weight of the body when the child moved about, and to aid in this the use of crutches was enjoined.

The subsequent history of this case will be interesting in various respects, but I am by no means sanguine of the success of any measure
which may afterwards be attempted to induce bony union. This impression was on my mind, probably in consequence of what I had recently seen in King's College in a case of the kind, under the care of Mr. Bowman. The leg of a boy about twelve years old, having the clear indications of a false joint, which had been present from early infancy, is faithfully represented by a cast from which figure 256 was drawn. The mould was taken as he lay in bed with the leg stretched to the utmost, and when he stood or walked upon the unsound limb the displacement and distortion are well represented by figure 257. The weight of the body so pressed the fragments downwards that the under one was bent forwards on the dorsum of the foot, and the end of the upper fragment actually rested on this part.

As it was evident that bony union, even if procured, would be of little advantage with the fragments in this distorted position, amputation was proposed, but Mr. Bowman, unwilling to resort to this proceeding, thought of trying resection, and of bringing the fragments straight during the after-treatment. This plan was accordingly followed, and with an admirable result as regards the straightening, as may be seen from the figure here displayed (258). The limb was treated as if for compound fracture, yet long after the skin had healed union
was still deficient. Being now more reluctant than before to take off the limb, Mr. Bowman resorted to Dieffenbach's proposal of inserting ivory pins into the ends of the fragments at various points. But here this plan failed also. This case, besides its interest as one which resisted some of the most potent agencies for the cure of false joint, exemplified the distortion and inconvenience resulting from this condition, and has afforded a remarkable proof how (at least) the distortion in such a case may be overcome.

The resection in the instance above alluded to was not accompanied with remarkable bleeding. The principal incisions were made on the inner side of the leg, and care was taken to avoid the tibial arteries and other important parts.

Since the fourth edition of this work, I have seen the patient from Royston, referred to in a preceding page, walking tolerably well with an artificial support to keep the fragments steady. Years ago I saw, in consultation with Mr. Paget, a case of a similar kind. Various operations have been performed to induce union by bone, but all had failed. An artificial support was recommended, and within twelve months we saw the child again walking with great facility, although no change had occurred as regarded union of the fragments.

I should certainly deem resection a last resource in the ordinary cases of false joint, occurring after fracture, in the leg in the adult, but should feel disposed to give it a trial when all other reasonable means had failed. The hazard of the proceeding, both as regards the size of the wound as well as the possible trouble from hemorrhage, should be duly weighed, however, although upon the whole, I think the risk worth incurring instead of amputation.

False joints in the femur need little notice here, and require to be treated in accordance with the general views laid down on this subject in the first section of the book. The introduction of a seton, incisions, either subcutaneous or for the purpose of introducing ivory or iron pegs, or resections, or the application of wires, must be conducted with reference to anatomy, and one grand object in any of these measures is to avoid the principal blood-vessels. In the middle of the shaft of the femur, where false joints are most frequent (with the exception of the neck of the bone, where such treatment as that under consideration is not required), the proximity of the superficial femoral artery and vein must induce the utmost caution in carrying any pointed or cutting instrument in this direction. Indeed, it may be deemed a rule that all cutting proceedings in such cases must be effected in front, or on the outer side of the thigh. I have seen resection of the ends of the fragments in many instances, and the result of my experience has been such as to induce me to advise caution and much consideration before applying the knife, as I have seen the loss of both limb and life ensue. One of the cases in my own practice was unsuccessful, the patient having died unexpectedly some weeks after, when the wound had all but healed. Another occurred to my colleague, Mr. Partridge, and was successful in all respects. The third, with Mr. Gay, of the Royal Free Hospital, answered no good purpose in the end.
Amputations on the lower extremity may now occupy attention.

The small toes occasionally require to be removed, in consequence of accident, disease, or distortion. If a portion of one can be saved, it may be well to do so. For the removal of a phalanx or more, proceedings similar to one or other of those described for the fingers (p. 282) will serve the purpose, and the directions need not here be repeated. Neither does it seem requisite to make any particular observations regarding additional toes which are occasionally met with. The surgeon, perhaps, interferes less frequently with these than with supernumerary fingers, and more persons come to mature age with such appendages than when the hand is in question.

For the removal of the whole toe a narrow bistoury should be passed up on one side of the proximal phalanx as high as the articulation; it should then be carried across the joint and down the opposite side, so as to make a wound similar in size to the first, when the toe will be separated. The knife when entered should lie almost flat against the phalanx; then, when it has been carried sufficiently deep, its edge should be directed against the lateral ligament, which should be put on the stretch by the surgeon judiciously twisting the toe whilst it is held in his left hand, and by the same means, too, he can make sufficient room to carry the knife across the joint without obstruction from points of bone: as soon as the latter object is effected, the blade should again be laid flatwise against the phalanx, and held so until it is about to be carried out opposite to where it has been first inserted. In performing such an operation, the surgeon's right hand may be either above or below the foot at his pleasure. Perhaps the point on which he is most likely to err is not carrying the blade sufficiently towards the foot; for the joint actually lies much deeper than a person not acquainted with anatomy might imagine.

Should the metatarsal bone be also affected, it may be removed after the separation of the toe, by extending the incision on the upper part of the foot, isolating the bone, and detaching it at its articulation with the tarsus; or if its proximal end is sound, the cutting forceps may be used as in the corresponding bones of the hand. I have strongly recommended the removal of a portion of a metacarpal bone when it is necessary to sacrifice a finger, and have, I trust, both written and shown enough to prove the advantage of such a proceeding; but, from all I have seen, I should be equally anxious to preserve the whole of a metatarsal bone, as the breadth of the foot should never, in my opinion, be diminished unless there is absolute necessity.

The great toe may be removed in the manner above described; that is, by lateral flaps. If the distal end of the metatarsal bone can
possibly be preserved, the foot will doubtless be much stronger afterwards than if it were removed, but it will often happen that the necessity for an operation depends on disease of the joint involving the end of this bone, and its amputation is therefore absolutely necessary; unless, indeed, excision be resorted to after the fashion alluded to at page 391 of this volume. I have also stated, on the same page, that excision of the metatarsal bone by itself should not be thought of here. In the event of amputation being required, as in an instance similar to the drawing at the page referred to, or the figure on this page, the operation may be performed thus:—An incision should be made along the upper and inner side of the metatarsal bone, beginning a little behind the supposed seat of disease, therefore, in some instances, over the internal cuneiform bone, and running round the joint as here represented (fig. 259); the skin and soft parts should next be dissected off, so as to insulate the end of the metatarsal bone, when the forceps can be applied behind the disease; or, if the whole bone must be removed, the distal extremity can be held in the left hand, so as to convert the bone into a lever, as by such a manœuvre its disarticulation from the cuneiform bone can be more readily effected. In the adult I have sometimes seen the bone so hard that it was requisite to use the saw, but in general the forceps will suffice, and I recommend that they should be placed obliquely upon the bone, so as not to leave a sharp point on the inner margin of the foot, as would be if applied at right angles. This latter direction may appear of no great moment, indeed, I do not consider it is so, yet if attended to, the operation will appear much more perfect. The flaps in this instance are after the fashion of an oval amputation, and I recommend them to be left more capacious than the drawing indicates.

In disarticulating the metatarsal bone, unless the knife is used very cautiously, there is every chance of wounding the anterior tibial artery, as it dips towards the sole of the foot; but in such an event the vessel can be readily secured after the separation; and, under any circumstances, it rarely happens that more than one, two, or three ligatures are required. In some instances,—indeed, I may say in many, occurring both in my own practice and that of others, I have seen much annoyance from continued bleeding in the deepest part of the wound, between the internal cuneiform and second metatarsal bones—perhaps, from the anterior tibial, or the extremity of the plantar arch, and after having in my own cases fruitlessly endeavoured to get a noose east round the bleeding point, I have been obliged to resort to pressure, which on these occasions has never failed. In such instances a little pellet of lint has been placed on the bleeding
point, then a larger, until the wound has been partially filled, when the whole has been compressed with a bandage applied moderately tight round the foot.

Occasionally in serofulous subjects the foot has the appearance represented in drawing 260. In this instance the swelling was so great on the inner margin, that it was doubtful if any partial amputation, unless it were Chopart's, would be of any avail; I determined, however, to be guided by what appeared during an attempt to save the outer side of the foot by a longitudinal operation. Being convinced that the internal cuneiform, and probably the scaphoid bone also, was diseased, as well as the metatarsal bone of the great toe, the external incision was made further back than for the operation last described: after separating the latter bone and the internal cuneiform, it was found necessary to scoop away a small part of the middle cuneiform, and also a portion of the second metatarsal bone, but thus the rest of the foot was preserved. I have the satisfaction of knowing that this patient had, after the lapse of two years, an excellent use of the foot,

which at that time presented the appearance exhibited in figure 261. The concave shape of the inner margin of the foot will be noticed, and the condition in which the second toe (now the first) is curved inwards is remarkable. Had this kind of distortion proceeded further, the foot might have resembled that referred to at page 392, in which it became so much twisted inwards, with the sole upwards, as to resemble a club-foot when the person walks on its outer margin.

If it should happen that the toes alone require removal, as might possibly be the case in frost-bite or in injury from violence, they may all be removed, at their articulations with the metatarsus, by transverse incisions so conducted as to leave soft parts to cover the ends of the metatarsal bones, both from the upper and under surfaces. No set rules seem requisite for such proceedings, which, moreover, are rarely if ever required.

If more than one metatarsal bone is affected, I am doubtful, for the reasons above alluded to, if a longitudinal separation should be
resorted to, and should be more inclined to perform a partial amputation in a transverse line, thereby removing the whole of the toes, whether diseased or not. Sometimes the tarsus is so extensively affected, that there need be no doubt about its entire removal; and in such cases, according to the current doctrines of the day, the surgeon has the election of dividing the foot at the junction of the metatarsus with the tarsus, in the manner recommended by Mr. Hey, or still further back, between certain bones of the tarsus, in accordance with the proposal of Chopart.

In partial amputation for disease of the metatarsal bones Mr. Hey at first removed the skin so extensively that no adequate covering was left for the remaining portion of the foot, and many months elapsed before the large surface cicatrized. He afterwards preserved a sufficiency of soft parts from the upper and lower aspects of the foot to make a good stump, and he has himself remarked that, "though the metatarsal bones, which had been removed, are usually about three inches in length, yet the mutilated foot was but one inch shorter than the sound foot, measuring from the heel to the root of the little toe." I cannot say that in the instances which have come under my notice the length of the foot has been so nearly perfect; but I can speak in unqualified praise of the advantages of the operation over the more extensive mutilation of amputation at or above the ankle.

As in most other operations, there are various ways of performing this one. The method I recommend is as follows: the lower part of the leg should rest on the margin of a strong table, and the ankle should be firmly grasped by the hands of an assistant: the surgeon should then endeavour to make out the projection of the proximal end of the metatarsal bone,—especially that of the little toe, and, if possible, the internal cuneiform, and with a strong bistoury should begin an incision a little behind one or other of these points, carry it forwards on the margin of the foot for three-fourths of an inch or more, and then across in a semilunar course, ending it on one margin as it has been begun on the other, a little behind one of the points above referred to: this incision should pass boldly down to the bones at once; but if any tendons or other textures have been left undivided, they should next be cut, and an assistant should draw the flap upwards; the operator should then forcibly depress the extremity of the foot, which he should hold in his left hand, and in this manner, by throwing the ligaments of the upper surface on the stretch, he can readily pass the point of the knife into the line of articulations, and whilst there is less danger of breaking it off, he, by this manoeuvre with the left hand, greatly facilitates the remaining steps of the proceedings: the fibrous textures being all divided, the incisions should be so conducted in the sole as to form a flap between the tarsus and roots of the toes, the knife being kept close to the under surface of the metatarsal bones as it is carried onwards. This long flap, with the short one above, will form an excellent covering to the ends of the bones.
AMPUTATIONS OF THE FOOT.

Drawing 262 illustrates part of the operation just described, and the stump when healed will present the appearance exhibited in figure 263.

If the internal cuneiform bone seems to project too much, its extremity should be cut off with the forceps or saw, as was recommended by Mr. Hey, or the bone may be wholly removed, as I have sometimes done with it in my own practice with excellent effect.

The proceeding of Chopart consists in the division being made in the line of articulations between the calcaneum and cuboid, astragalus and seaphoid bones. From the joints being larger, and the bones less firmly knit together than in the seat of Hey's operation, amputation through the tarsus is much more easily performed; but it should not be preferred on this account, and it ought to be extreme necessity only, from the nature and extent of disease or injury, which should induce the surgeon to sacrifice so large a portion of the foot. It is rare to see injuries of the foot which at the first dressing require any partial amputation. Disease necessitating this step may follow afterwards, however, and very frequently strumous affections of the tarsus demand such treatment in the course of time. It is often difficult in such cases to determine the extent of disease, but it will be of great conse-
quence to make out that the astragalus and os calcis are sound, for, under such circumstances, whatever the amount of swelling in the soft parts, he will be justified in performing this operation in preference to any more extensive mutilation. Figure 264 represents the forepart of the tarsus in a state of incurable caries which had resisted all treatment for many years. Here amputation of the leg was proposed, but at my suggestion Chopart's operation was performed. The result was most satisfactory. In such an example as figure 265,

Fig. 265.

the separation of the dead parts might have been left to nature, but the process would have been tedious, and I therefore deemed it better to use the knife. I have seen an excellent stump in a similar case, where all that was considered requisite was division of the bones with the saw. It is not always, however, that the work is so perfect, and if the surgeon interferes, it will be better to preserve flaps sufficiently large to cover the ends of the remaining bones. The dotted lines on drawing 265 are very similar to those recommended for Hey's operation, excepting that they are placed nearer the ankle. The whole proceedings should be similar; a small semilunar flap being preserved from the upper surface, and a large one from the sole. In disarticulating, if the left hand is used in the manner above adverted to, the bones will separate very readily as soon as the point of the knife is applied to the ligaments put on the stretch. The projection of the scaphoid bone is the only prominent point which can be referred to as a guide, although on the living body it may be impossible to feel it in consequence of the swelling of the soft parts; but these joints are so very easily opened, by any one acquainted with the anatomy of the foot, that there can be little difficulty in accomplishing the operation. The future utility of that part which is left has been questioned by some; but from what I have seen of these partial transverse amputations in the foot,—and my personal experience in such operations has been considerable,—I should in general prefer them to more extensive mutilation at or above the ankle. It has been asserted that the heel is drawn so much backwards and upwards, particularly in the case of Chopart's operation, that the weight of the body will be thrown on the cicatrix and the anterior ends of the bones; but if the stump be kept in good position during the dressing, I do not think that there is much cause for anxiety on this score.
AMPUTATIONS OF THE FOOT.

Figure 266, taken from one of my own cases, exhibits a good stump in this locality.

I have met with one example in my own practice which caused distress and necessitated further interference. Having made an excellent stump of this sort on a young man’s foot, it was found as he attempted to walk upon it that there was induced a kind of turn or twist backward, whereby the heel was thrown up and the cicatrix downward. In this condition there seemed a tendency for the ends of the tibia and fibula to slip downwards and forwards, causing severe strain upon the lateral ligaments. Thinking that the muscles of the calf of the leg induced this malposition, I divided the tendo Achillis by a subcutaneous incision, but, although this let the heel down, I was ultimately obliged, owing to a tender state of the stump, to remove the two bones at the ankle-joint.

This is the only instance of a painful stump after Chopart’s operation which has ever occurred to me, and I am now disposed to attribute it to a peculiarity of constitution more than to any imperfection of the proceeding recommended by Chopart. My reason for so doing is that the stump at the ankle became a tender one also, although as regarded appearance and shape, it looked as well as any I have ever seen.

The bleeding during these proceedings on the toes or foot can be conveniently and efficiently arrested by an assistant compressing the tibial arteries at the ankle, or, if greater security is desired, a tourniquet may be put on the leg, or at the knee, as represented in the chapter on the means of suppressing hemorrhage.

In performing these latter operations some transfixed the sole of the foot with a small catlin, and cut the flap from this part at the first: others instead of transfixing proceed from the surface inwards; some open the joints below, others at the side, but I give the preference to the plans described above. I would not, however, on all occasions limit myself to the articulations. If, for example, the proximal ends of the metatarsal bones could be saved, I would assuredly do so, making a semilunar flap on the upper part of the foot, as already directed, only a little nearer the toes; then another below by cutting from the surface of the sole obliquely backwards and upwards towards the bones; next I would clear around each bone a proper space for the saw or forceps, and then with one or other of these would divide the bones. I have seen a most excellent and useful stump saved in this manner. If the posterior parts of the cuboid and scaphoid bones could be preserved, I should do so, dividing them in their middle with the saw. In 1845, in performing Chopart’s operation, I imagined that the flaps were somewhat scanty, and sawed off the end of the astragalus with excellent effect: in another instance I have met
with ankylosis in the line of division, and, under the impression that I had missed the articular, accidentally, in making further use of the knife, opened the ankle-joint. The saw was used to divide the bone, no harm resulted from the wound of the joint, the incisions healed most kindly, and in both the stumps were equal to any I had ever seen.

In the dissecting-room one seldom hears of any amputations in the foot, excepting at the joints, Hey’s and Chopart’s being the favourite exercises; but occasionally it may be well to keep these hints in view. The recommendation seems like a recurrence to the old and rude method of chopping off a part with the aid of the chisel, mallet, and block, or of severing the disease by a single grasp with strong forceps, as used to be the summary work of ancient surgeons; but it must be kept in mind that in reality the preservation of flaps forms the most important feature in the modern operations; indeed, I am inclined to suppose that Mr. Hey, if we may judge from his own remarks, seemed to consider this as the chief feature of his own method, for in the first instance in which he preserved flaps he did not limit his incisions between the tarsus and metatarsus, but actually removed a considerable portion of the former.

Although amputation at the ankle joint had received the sanction of Sabatier, Lisfranc, Velpeau, Baudens, and others, the mode of procedure seemed to offer such poor promise as to the condition of the stump, that one cannot be surprised at the indifference shown on the subject. The coverings to the ends of the tibia and fibula were saved from the skin over the arch of the foot, and behind the ankle, and sometimes from the sides below the malleoli. It is easy to perceive that these, however ample in extent, would be so thin as to form a very imperfect cushion to support the weight of the body, and judging from the defective protection to the ends of the tibia and fibula we cannot be astonished that amputation in the leg should have been selected in preference.

The operation proposed and performed by Mr. Syme does away with such objections, however, as its principal feature is that of retaining the skin on the lower part of the heel to form the end of the stump. This part, intended by nature for the body to rest upon, has been thought most likely still to form the very best cushion though the heel-bone is removed. Mr. Syme performed his first operation of the kind in September, 1842, and published the particulars in the London and Edinburgh Monthly Journal of Medical Science for February, 1843; he afterwards elucidated the subject in a series of notices in the same journal, and as the crowning merit adduced a number of cases most successfully treated in this peculiar manner by himself and others.

The circulation may be commanded by any of the methods alluded to in former pages, and the operation is done by Mr. Syme somewhat in the following manner:—A lunate incision is made across the instep from one malleolus to the other, and then the knife is carried in a semilunar direction along the sole of the foot, the points of both
incisions meeting on the sides a little below the malleoli, as indicated in figure 267. The soft parts are further divided and detached, in such a manner as to permit the removal of the foot: finally, the saw is applied to separate the malleoli, and, if necessary, a thin plate of

the articular surface of the tibia. The tibial arteries, and such branches as may bleed, being secured, the hard tissue from the sole of the foot is brought up against the ends of the bones; union by the first intention is promoted, and the treatment, generally, is conducted in accordance with the ordinary doctrines of surgery.

The proceeding above described is by no means so easy as an ordinary amputation in the leg; but, connecting the advantages peculiar to it, the surgeon should not on this account hesitate to perform it. A tedious and protracted dissection is required to disarticulate and to separate the skin from the projecting part of the os calcis; and, moreover, it is barely possible to avoid cutting the integument in this locality. But, as regards this latter point, there need be no anxiety, as an opening here is rather an advantage than otherwise, for it permits the free escape of pus, should any form in this locality. Occasionally some sloughing takes place on the lower flap; but there seems no danger of serious evil from this. Mr. Syme recommended that care should be taken to preserve the posterior tibial artery of as great length as possible, to insure a sufficient supply of blood for the lower flap, and has, moreover, strongly inculcated the propriety of not twisting or stretching the soft tissues, for fear of after sloughing. With this view he has advised that the skin of the heel should be dissected off the os calcis before the astragalus is disarticulated.

Mr. Lyon of Glasgow, and Drs. Handyside and Duncan of Edinburgh, successfully, with slight modifications, followed this practice. Dr. Handyside has kindly favoured me with a cast of one of the stumps made by him, and its appearance is most satisfactory. Instead of making semilunar incisions above and below, this gentleman makes them on the sides of the foot, the points meeting above and below;
but for further elucidation of Dr. Handyside's views, I must refer to an able paper by him in the Monthly Journal of Medical Science for October, 1845. Dr. Duncan stated to me his impression that a preliminary subcutaneous division of the tendo Achillis might facilitate the resection of the heel; he followed the steps inculcated by Mr. Syme, and the figure (268), taken from a cast which he had the politeness to forward to me, exhibits the condition of a stump made after this fashion.

It has very frequently been remarked after amputation at the ankle, that a considerable extent of the under flap sloughs, and in some instances almost the whole of it has been lost in this way. It has often been observed, however, in such cases, that the stump has turned out an excellent one after all. But even when the soft parts appear scanty, an excellent stump may be formed by taking away half an inch, or a little more, of the bones. Partly on account of the sloughing, and partly because it has been found that a shorter under-flap than that first proposed will suffice, Mr. Syme has latterly carried his incision further back in the sole of the foot. With such an external wound as that indicated in figure 269, I have been satisfied as to the results, and the
AMPUTATIONS OF THE FOOT.

division of the skin so much further back than in the operation originally performed permits the more easy and more rapid removal of the foot. It may happen after this amputation, as after most others in the long bones, that disease may arise in the osseous surface where the saw has been applied. I have seen an excellent stump made in such a case by opening up the cleatrix and sawing off a portion of the bones. The operations will suit for accident (as has already been stated in my observations on compound luxation of this joint at page 320), as well as disease; and many such feet as that represented in figure 269 (a likeness of disease in the tarsus for which amputation in the leg was resorted to), will be best treated in this way. Even should the ankle-joint itself be the principal seat of disease the operation may be performed,—for it is seldom that there is more than a thin layer of the articular surface of the tibia affected in such cases. If length of limb and stump, and a perfect covering to the ends of the bones, be advantages, certainly this proceeding affords them; and there are other seemingly good reasons for adopting such an operation; for which, however, I must refer the reader to my notice of amputation at the knee.

Instead of taking away the portion of the os calcis to which the tendo Achillis is attached, M. Pirogoff, of St. Petersburgh, proposed to reserve this portion by sawing the bone vertically. Mr. Ure, of St. Mary's, and my colleague Mr. Partridge, were among the first to perform this operation in London, and it has since obtained great favour in all parts of the world. For myself, I invariably give it the preference, and latterly, when the ends of the tibia and fibula have been sound, I have generally reserved the malleoli. The retained portion of the os calcis fits nicely between them, and in only one instance have I seen reason to regret leaving the end of the calcaneum. In this case caries occurred on the cancellated structure, and a subsequent operation was required for its removal. The outer incisions are much the same as for Syme's operation, but they need not be so far forward as in figure 267. The dotted line in figure 269 is nearly correct, and instead of dissecting out the end of the os calcis from the surrounding skin and its attachment to the tendo Achillis, it is sufficient to clear a space about the middle of the bone—or rather nearer the back part—so that the saw may be applied. It is thought an advantage to divide the bone obliquely, so that the upper part shall be shorter than the under. Before the saw is used all the soft parts must be so divided that, when it has done its work, the astragalus and front part of the os calcis, with all in front, are separated by the section. I am so satisfied of the advantage of dividing the tendo Achillis in this operation, that I recommend it as a preliminary step, to be performed much as in a case of talipes. The lower flap thereby fits better, and the bed of os calcis is not disturbed by the action of the muscles of the calf of the leg. Sketch 270 shows the appearance of the stump in one of Mr. Partridge's cases. The child, when I saw it last, was walking nimbly, and with a halt scarcely to be detected.

I look upon this operation as the greatest modern improvement in
amputations, and it is difficult to say to which of the two distinguished surgeons whose names are associated with it most merit is due. In my estimation, the method of Pirogoff is the best; but the reservation of the skin of the heel, the great feature of the operation, is the work of Mr. Syme, and without this original idea, we should probably never have had Pirogoff's suggestion.

Amputation in the leg may be effected in any part of its extent, according to the nature and seat of disease or injury. At one time it has been the fashion (this word being more applicable to the practice of surgery than some imagine) to amputate close above the malleoli, at another close to the upper end of the tibia, and, often, the incisions have been made at all the intermediate distances; all these having been done by the same surgeon at different periods in his practice, whilst others have adhered, when circumstances would permit, to one particular part. Mr. Hey, finding that the stumps which he made immediately above the ankle did not on all occasions heal kindly, resorted at last to the middle of the leg, where he could procure more ample covering to the ends of the bones; and my own experience leads me to think that he was right.

In by far the greatest number of amputations in the leg which I have witnessed, the incisions have been made in its upper third, and I have myself pursued a similar plan. Most of the patients have been in hospitals, and the common doctrine that persons in this rank of life can more readily procure a wooden leg, on which the body may be supported with the knee bent, than any other substitute having the resemblance of a natural leg and foot, has probably been the chief reason for operating so high. If the knee is afterwards to be kept bent, a long stump projecting behind will be inconvenient, unseemly, and exposed to injury. But the knee may be kept straight, and an artificial limb applied, much lighter in appearance than the clumsy apparatus in common use, equally efficient, and also as moderate in price. This method, though still followed on the Continent, and of old date among our own surgeons, having been practised and highly extolled by Charles White of Manchester, has been almost entirely neglected till of late, when it has been revived by various practitioners. I have myself been in the habit of preserving nearly half of the leg, more or less, with the object of continuing the movements of the knee, and having such a substitute applied as that referred to. Figure 271 is an example of a stump from one of my patients, and the other (272) represents the substitute in question. The socket at the top of the pin (made of strong leather or of willow-wood), being well padded within, is fixed on the stump, and the straps serve to attach it above
the knee. The case is so fitted to the limb that the greater part of the weight of the body (possibly all) may be sustained by the upper end of the tibia. I have seen a person thus provided move about as freely as if no loss had been sustained, and from all I have witnessed of the practice, am strongly inclined towards it in most cases, when amputation in the leg seems requisite. Dr. King, of Glasgow, recommended such a machine, and Dr. Laurie of the same city, also one of the modern advocates for this plan, mentioned to me that one of his patients was frequently in the habit of walking twelve or fourteen miles a day with the utmost ease on such a limb. I have seen a circular plate at the bottom moving on a pivot in the end of the pin, add considerably to the facility of standing, or rather turning on this support.

I have sometimes observed that it was more easy for the patient to rest the body on the bent knee than on the perpendicular stump, however well the latter may have been formed; but in the generality of instances the plan will be found to answer admirably well: and if the stump be made of such a length only as to fix into the socket, should it be found that the weight of the body cannot be sustained in this way, the projection when the knee is bent will appear so trifling that little objection can be taken to it.

When the surgeon has a choice of site, he should prefer operating about the middle of the leg. A stump of sufficient length for fixing any apparatus will thus be left, whilst at the same time the soft parts bear such proportion to the bones, that an excellent covering to their ends can be provided; whereas, if the incisions are made nearer the ankle, this is not so certain. The operation may be conducted in the following manner:—The patient being placed on a firm table, and properly supported by assistants, one of whom should have charge of the part about to be removed, with a tourniquet applied at
the knee or groin (pp. 27, 28), or the vessel commanded at the latter point with the fingers (p. 24), the surgeon should pass an amputating knife, about seven inches long, from one side of the limb to the other, close behind the bones, and cut a flap from the back of the leg, about three or four inches in length, proportioned to the bulk of the member; next he should draw the blade across the fore part of the leg with a semilunar sweep between the points where he has transfixed; the large flap behind and the small one in front being drawn up by an assistant, the operator should then carry the knife round and between the bones, a little higher than the line of transfixion, and having cleared a space for the saw, that instrument should be applied and the separation of the part effected.

To the beginner this proceeding will be the simplest; but to any one who has confidence in the use of the knife, I recommend the following. The heel of the instrument should be laid on the side of the leg furthest from the surgeon, and the blade should then be drawn across the front, cutting a semilunar flap of skin, until its point comes opposite to where the edge was first laid on; without raising the instrument, transfixion should next be made behind the bones, and the rest of the proceedings conducted as in the other instance. The operation when done in this manner will look somewhat more elegant (if the term be applicable to any such proceeding), but can scarcely be said to possess any other advantage.

*Fig. 273.*

Drawings 273 and 274 will further elucidate this latter description: the one (273) exhibiting the first position of the knife, and the outlines for the two flaps; the other the attitude after transfixion, and as the blade is being carried downwards. Two operations were done on the subject according to the method last referred to; and, in the lower part of the leg (fig. 274), as soon as the knife was thrust across behind the bones, the artist cried "stop," and pencilled the design as it is represented. I may here call attention to the acute angle at the junction between the two flaps: the incision is seemingly further back
than there is any occasion for, and this will be most likely to strike those who may have witnessed only the method by transfixion first, and the transverse incision afterwards. By the latter proceeding the anterior and posterior do not correspond very acutely in their respective lengths, and so when the stitches are inserted there is always a bulging irregularity at each angle,—the wound in the skin of the

posterior flap being doubled on itself, as it were, whereas by carrying the incision backwards on each side of the limb in the first sweep, as above recommended, the point of the knife can not only be more readily inserted for transfixion, but also the surfaces will come more accurately together, and be better proportioned to each other than by the other method.

The surgeon has not always the opportunity of selecting such a place as he might prefer for his operation, and is occasionally forced to amputate very high. When this is the case, perhaps the nearer to the tuberosity of the tibia that the operation is performed so much the better. The popliteal artery can then be secured, when probably one ligature will suffice, instead of three or more, as will be required, two tibials and a fibular, if the incisions are made a little lower. If the limb is muscular, a fleshy mass, formed chiefly of the gastrocnemius and soleus, will be left, which will with difficulty be covered by the skin: for the latter retracts more readily here than the muscles. I have seen a large granulating surface, on the end of the muscles projecting between the edges of the wound, remain open for months, and from all I have witnessed in such cases, I believe that the surgeon would do well to cut away some of the muscular fibres, after the flaps have been formed, so as to bring them to a level with the skin. Such a proceeding will convey an impression to those who are inclined to be hypercritical, of a want of skill on the part of the operator; but he may console himself with the consideration that the practice is inculcated by Mr. Hey, who distinctly recommends it as advantageous. In the limb emaciated by long-continued disease, no

Fig. 274.
such trouble is experienced, and an excellent posterior flap can always be made at once.

In the upper third of the leg it is often extremely difficult to seize and tie the vessels; so much so, indeed, that I have seen Mr. Liston in despair, transfix the soft parts near the bleeding point with a tenuculum, then surround them with a strong thread, and leave the instrument to separate with the ligature. In this part of the leg venous hemorrhage is troublesome occasionally, when the tourniquet is slackened, and it is often so when pressure by the fingers in the groin is resorted to; it will generally cease as soon as the surfaces are approximated, but until then, while the arteries are being secured, a little pressure with the point of the finger on the veins will stem the flow.

In whatever part of the limb the incisions are made, I invariably preserve a semilunar flap in front, varying in length in different cases, from half an inch to one inch, or more. I prefer this to the straight incision across the front, recommended by Mr. Hey, believing that the opposite surfaces will thus fit more accurately to each other.

The crest of the tibia often seems so sharp and prominent, that it is well to remove it with the saw or forceps. I have seen it sometimes cause an ulcer in the skin, and exfoliate through the opening.

The limb should always be held nearly in a straight position, and I am partial to the same attitude in the after-treatment for the sake of retaining the movements of the knee if required. If the posterior flap be somewhat deficient in length, the surfaces can be most readily approximated by bending the knee, but the skin in front being thus put on the stretch, is more apt to be injured by the spine of the tibia, and the straight attitude is not so easily regained afterwards.

Much has been said about the necessity of the surgeon's standing on a certain side of the limb in these operations. Some of the highest authorities have contended for the one side; others, equally good, have asserted that the opposite is better. It has been said, that as the fibula, in some part of its course, is a little behind the line of the tibia, there is danger of the point of the knife passing between the bones, if the instrument is thrust from the inner side; but it seems to me that, if the operator is not on his guard, it may happen when passed from either side. I have seen the occurrence twice on the living subject, and recommend that, on whichever side the surgeon places himself, he should always avoid the possibility of such a piece of awkwardness. I find one author, who insists on the advantages of invariably passing the knife from the outer side, equally strenuous in advising the surgeon to stand on the inside when he applies the saw, so that the fibula may be divided first; and to follow up these directions it must of course be necessary to change sides between the use of the knife and the saw! another, who recommends transfixion from the outer side, also advises that the fibula should be first cut; but he says nothing about the change of position, and it will be found exceedingly awkward to accomplish the section in this way; indeed he must stoop, or perhaps get upon his knee, in order to bring the handle of the saw below the bone. Some have advised that
the operator should always stand on the patient's left side, so that, with his own left hand, he may keep the part about to be removed in a proper position for the application of the saw; for it may happen that the assistant who has charge of the lower part of the limb will keep it so high as to cause the instrument to become locked in the groove, or else may depress it so as to snap and splinter the bone. But it is erroneous to suppose that in either of these events the fault always lies with the youth who holds the condemned part, for the same things happen if the limb above is not properly held, and as it also may be depressed or elevated, it follows that the surgeon's left hand must be equally useful above the wound as below it;—consequently, that if he is to trust to himself to steady the parts properly, he may have his left hand either above or below, and therefore be either on the patient's right side or on his left, as may otherwise be most convenient.

For my own part, I think it a matter of indifference on which side the surgeon stands: the knife may be pushed between the bones from either aspect, and on whichever side the person who guides it is placed, the work of the saw may or may not be properly accomplished. If a well-set instrument is used, there seems no good reason for insisting on the division of the fibula first, further than that this bone cannot be kept so steady after the tibia is cut, and it is therefore more difficult to use the saw upon it. To effect this last object, here, as in other parts of the body, the hand should always, if possible, be above the level of the blade. If the surgeon always stood on the inside of the leg, then the cutting edge could be placed obliquely, so as to give the best opportunity of using it in the most favourable position for the division of the fibula first, and also afford the most easy and efficient attitude for his own arm and body. If, however, he invariably stands on the outside, it is evident that, unless the limb be much turned inwards, the fibula cannot be cut first, without the wrist being most disadvantageously depressed; but the limb and saw may be so held that the division of both bones can be accomplished about the same time, whilst the heel of the instrument is but a very little under the horizontal line. It seems to me, however, that the necessity for the division of the small bone before the large has been made a matter of too much importance.

If the operator resolves on dividing one bone before the other, he should see that the saw is of sufficient breadth: indeed, it is of more consequence to look to this in the leg than elsewhere, for if the amputation is very high, the great thickness of the tibia in this situation should not be overlooked.

By sawing the bones individually, I have in certain instances observed that the fibula has been left somewhat longer than the tibia. This is a mistake which should be carefully avoided, for the prominence will not afterwards admit of any pressure on the part. Some have recommended that the fibula should actually be cut shorter than the other bone.

When the amputation is very high, it has been proposed that the
head of the fibula should always be removed for the sake of forming a better stump. I saw this practice extensively put into execution in the Edinburgh Hospital, by Messrs. Liston and Lizars; but in consequence of the frequent occurrence of inflammation and suppuration within the knee, it was at length wholly abandoned. It has been averred that the synovial capsule at the head of the fibula very frequently communicates with that of the knee, and that, therefore, when the small bone is removed on these occasions, there is every probability of the large joint being opened. I have not myself observed the communication to be a frequent occurrence; but the partition is on all occasions so very thin, that there will always be a likelihood of opening the knee in such a proceeding. Sometimes these gentlemen dissected out the end of the bone after the saw had been used; at other times, when the amputation was very high, the tibia alone was cut with this instrument, and a knife was carried round the head of the small bone, from within outwards, whilst the limb was forcibly abducted, and the fibula used as the lever. Unless, however, the bone be extensively shattered, or in a state of disease, it never should be entirely removed. In the present edition I leave the above paragraph much as it was originally written, both as a substantial fact and as a link in the history of amputation in the leg. Such an operation is, I believe, now out of use.

The amputation in the leg which I have recommended, may be deemed that with the single flap, originally proposed by Verduin; it will be observed, however, that such a portion of skin in front is preserved, that it may actually be called a double-flap operation. I have seen even a larger portion left in front, so as to give the proceeding still more the character of the double-flap operation; but one-half of the stump appeared to me so like a bag of skin, containing pus within, that I was not impressed with any advantage which the method presented, unless it was that it allowed the surgeon to depend less on the bulk of the posterior flap, and thus enabled him to avoid the inconvenience of a large mass of flesh, such as has already been adverted to. I should rather, however, dissuade from leaving a long flap in front, as there is thus a probability of the cicatrix being more in the middle of the stump than towards the front, where, properly, it should be. The views of Mr. Teale, however, induce me to lay less stress on these points than heretofore.

I have also seen lateral flaps made after the manner practised by Roux, by transfixing from before backwards; but although the operation was done by an adept, the stump was the worst I ever saw. A double or single flap might be preserved from the tibial or fibular side, should it be deemed necessary; but such proceedings need no separate description here, as they can scarcely be deemed among the regular operations of surgery, and any one possessing a moderate share of anatomical knowledge, and dexterity with the amputating instruments, can have little difficulty in preserving a covering, of skin at least, from any side of the limb.

Whichever proceeding is followed, and in whatever part of the leg
the incisions are effected, the general rule of preserving an inch too much rather than the least portion too little, should always be kept in view. The surgeon, three or six months after amputation, will have more reason to be well satisfied with a stump which looked clumsy at first, than with another which possessed all that finical neatness which may have captivated the spectator at the time, but will make an indifferent appearance when compared with the other at some future date. I have seen the posterior flap too long in this situation. The operator apparently had a dread that his flap would be too short, and had made sure against this fault, by reserving nearly the whole textures on the back of the limb.

Hoin, in 1764, performed amputation at the knee-joint by making a semilunar incision in front, extending from one side of the knee to the other, then passing through the joint, by dividing the mucous, lateral, and crucial ligaments, and reserving a long semilunar flap behind.

The operation has been varied in many ways; by taking a longer flap from the anterior surface, as recommended by Becard and others; by making lateral flaps, as was done by Rossi; by circular incisions, three or four inches below the patella, after the manner of Velpeau; and by making three flaps from the circumference of the upper part of the leg, as was successfully done by Pancoast. None of these modified proceedings, however, are in my opinion, with due deference to the objections of Velpeau, equal to the operation originally done by Hoin, provided the posterior flap be made sufficiently long, and the anterior incision be kept somewhat below the level of the joint. Considering the breadth and irregularity of the articular end of the femur, it is evident that it must be difficult to procure a sufficient cover without trusting to the skin alone in some parts, and one cannot but imagine that the vast comparative size of articular surface must add to the danger of the patient.

It might serve those deeply interested in the history and progress of this operation to look at former editions of this work; but to keep within reasonable space, I now omit and modify much previously written, although I still consider the subject of engrossing importance. Elsewhere, in my "Lectures on the Progress of Anatomy and Surgery during the Present Century," I have endeavoured to do justice to Mr. Carden, of Worcester, for his remarkable and, I may almost say, single-handed efforts to introduce amputation at the knee-joint as a legitimate operation in surgery. With certain exceptions mentioned in that book, few efforts have been made by others to elucidate so great a question in surgery, and for the present Mr. Carden's words may be deemed paramount.

Instead of taking the main flap from the calf, as done by Hoin, Mr. Carden has taken the skin over the front and upper part of the tibia to cover the condyles, and has left a short flap of skin and other tissues behind. The outline of the operation will be readily understood by these illustrations, fig. 275 showing the incisions on the surface, and fig. 276 the appearance of the stump on approximation of the cut surfaces.
Hitherto, in amputations low down in the thigh the surgeon has invariably been obliged to saw through the bone several inches above its lower extremity, so that there might be sufficient soft parts to make

Fig. 275.

a good stump. It has always been the practice, too, in examples of disease of the knee-joint requiring this operation, to shape the flaps from a part of the limb considerably above the joint. In that form of disease, for example, familiarly termed "white swelling," the flaps have always been cut above the swollen textures; and if by chance an abscess has been cut into,—having extended further up than was expected,—the surgeon's skill and judgment have been questioned, and it has been supposed, especially by those who have not taken the trouble to follow out the subsequent history of the case, that the incisions have, erroneously, been kept too low: but Mr. Syme has proposed to divide the parts much lower than has ever been done in amputations in this locality. The proceeding may in some respects be deemed a modification of Hoin's amputation at the knee,—the principal difference being, that instead of separating the leg at the joint, the saw is carried through the femur a little above the articular surfaces. Mr. Syme, in his observations on this operation, published in the London and Edinburgh Monthly Journal of Medical Science for May, 1845, adduces various reasons why in many instances it should be selected in preference to any other; he alludes to a prevailing error, that has obtained with most surgeons, regarding the supposed necessity for removing on such occasions the swelling around a diseased joint, and to show that there is no such necessity, refers to the success following excisions of joints, when the articular surfaces, and thin slices of the contiguous bone are alone removed; for, in these instances, if the ulcerated and carious parts are taken away, the swelling of the surrounding tissues, however great it may be, is certain to subside. He is also of opinion that there is greater danger of evil consequences to the bone when the hard tissue of the shaft is cut, than when the
saw is carried through the spongy texture close upon the articular surface, and seems, with Cruveilhier, to dread the occurrence of inflammation of the medullary sheath when it is injured and exposed in the ordinary proceeding.

There are many instances of incurable disease of the knee-joint where the serious mischief is limited to little more than the articular surfaces: in such cases, however great the surrounding swelling may be, as also in all examples where the whole of the leg must be sacrificed, whether for injury or disease, Mr. Syme proposes to substitute this operation for the proceedings hitherto performed higher up; and in several cases of the kind which he has published, and many occurring in my own practice, the results have been so satisfactory that I am disposed to consider the operation well worth the attention of the profession.

Amputation at the knee may be done in the following manner:—
The circulation being arrested as usual, the surgeon, standing on the outer or inner side of the limb as he may feel disposed, should lay the heel of an ordinary amputating knife, such as is used for the common operation in the thigh, over one condyle of the femur, draw the blade to the other condyle across the front of the joint in a lunated course, on a level with the middle of the patella, and divide the tissues down to the bones; the little flap should then be pulled upwards, and the knife should again be applied so as to cut the quadriceps extensor immediately above the patella; the point of the blade should then be pushed in at one end of the wound, thrust behind the femur, and made to appear at the other end, when it should be carried downwards in the line indicated on drawing 277, so as to make a flap from the calf of the leg, about eight or ten inches in length in proportion to the thickness of the limb; this flap should now be slightly retracted, when the knife should be carried round the bone a little above the condyles, to clear away for the saw, which should then be applied to complete the separation. The popliteal artery, and such others as require liga-
ture, should next be secured; the posterior flap should then be stitched to the parts in front, and the after-treatment may be con-
ducted as with the ordinary operations. Drawing 278 exhibits a stump which was made after this manner, and the particulars of the case were published in the Lancet, July 19, 1845. I have seen the stump long after, and without exception, I deem it equal to any I have ever made in the thigh. The man has repeatedly walked forty miles a day with a very indifferently made artificial leg, and once accomplished a hundred and twenty miles in three days without the slightest damage to the tissues.

The proceeding above described may be modified according to the taste or discretion of the surgeon: the posterior flap may be made first, as in the leg; but I imagine that it will be a little broader if the knife be first used in front, and the saw may be applied at the endyle, or higher, as may seem requisite. The point which probably most demands attention is, that the posterior flap may be made sufficiently long: it appears almost absurd to recommend that the whole calf of the leg should be reserved for this object, yet I concur with the recommendation of Mr. Syme that the flap in question should be "to the full extent of the fleshy part of the gastrocnemii muscles," and longer than indicated in fig. 277. The cicatrix will be in front; and it is, perhaps, one of the most striking features of this operation that the principal coverings to the stump in the thigh are reserved from the leg.

If there be much swelling around the joint, there may possibly be some trouble in seizing the popliteal artery, and the posterior flap will not bend so easily as the tissues a little higher up; but, as already stated, the tumefaction will soon subside: and though it may at first appear that the flap is somewhat too long, the retraction will soon be such as to give the stump a most satisfactory appearance. This fleshy part of the leg should form a thick and firm covering to the end of the femur; and on this account, as well as the comparative thickness of the bone, as also the length of the stump, the result may probably prove altogether more satisfactory than that following any other amputations in the lower third of the femur.

Further satisfactory experience in this operation, and various
favourable reports from America, induce me to recommend it strongly, with this exception, that in many of the instances of disease above referred to, I should feel more inclined to resort to resection of the knee-joint.

Amputation in the thigh may be performed in a variety of ways: perhaps the following, which is in most respects similar to that originally done by Vermale, may be found as efficient in every respect as any other, especially in the lower third of the member, although it will be perceived, from what is stated afterwards, that I give preference to other methods. The femoral artery being commanded, as described and represented at pp. 24 and 26, the surgeon, standing on the outside of the limb, should grasp the soft parts on the outer side of the thigh between his fingers and thumb, and having drawn them as it were from the side of the bone, should pass the knife from before backwards, or rather from above downwards, as is here represented (fig. 279), and then cut downwards and outwards so as to form a flap,

Fig. 279.

the extremity of which is pointed out by the dotted line on the outer side; next, the knife should a second time be introduced in front, and carried backwards or downwards in a line with its original course, but on the opposite side of the bone, when by cutting again downwards and towards the surface, as partly indicated by the other dotted line, the inner flap is formed: both of them should then be drawn upwards with considerable force by the hands of an assistant and an incision made round the bone, an inch or more higher than the place of transfixion: the saw should then be applied in the course of this last cut, and the separation completed by division of the bone. In transfixing, the point of the knife should be thrust directly down to the femur, with which it should be kept in close contact as it is carried round to the opposite surface, and this process will be greatly facilitated by grasping the limb as directed.
The assistant who has charge of the flaps should not forcibly elevate the one first made, as the knife is thereby prevented from passing readily across the limb the second time: he can scarcely, however, be too energetic after the other is cut in drawing both upwards, so as to give plenty of room for working the saw without rubbing against the soft parts. The main artery is not divided until the second flap is formed; indeed, Vermale had this in view when he made his external wound first; but I do not think it of much consequence whether this vessel is cut across first or last, provided the surgeon takes sufficient care to have the vessel properly commanded above, or has sufficient self-confidence, in the event of an accidental mistake, to grasp the limb, and thus whilst he may arrest the bleeding with one hand he can seize the vessels with the forceps held in the other. I deem the proposal of saving the artery to the last as of little consequence, and am generally in the habit of making the inner flap first instead of the outer, as I can thereby see the progress of the knife much more clearly during the second thrust.

Drawing 280 exhibits the appearance of the stump with lateral flaps. It will be found during the dressing, that care is required to keep the soft parts in their proper and natural position: they have a tendency to fall backwards, and thus the end of the femur comes nearer the anterior angle of the wound than it should: moreover, it will be found in the course of a few weeks, that the parts behind are all more drawn upwards than those in front, and at last the bone seems to have a very scanty covering. To provide against the latter occurrence it may be well to leave the flaps a little longer behind than in front, and for the former, the bandage, properly applied after the first ten or twelve days, will do all that is required, if the dresser is careful in keeping the soft textures well forward during its adjustment.

In fig. 279, the point of the knife is nearer the table than it should be on the living subject, for by passing it somewhat obliquely to the long axis of the femur the soft parts can be kept longer below (or behind) than they might be if transfixion were made at right angles. The young surgeon should remember, however, that if he slopes the knife in this way, and if the knee is much bent, as it often is in cases of white swelling, there is a risk of thrusting its point into the calf of the leg below, as I have actually witnessed on the living body.

The projection of the bone through the anterior part of the wound, when the amputation is above the middle of the thigh, has been found so difficult to counteract, in consequence partly of the action of the
psoas and iliacus internus muscles, and the weight and contraction of the muscles behind, as to induce many surgeons who practise the flap operation to select the covering from the anterior and posterior surfaces; in fact, it is now generally the custom with some operators to make anterior and posterior flaps in all parts of the thigh, and I have myself often resorted to this method, partly with a view to obviate the ill effects above referred to, but chiefly because I find it to possess an advantage over the other, which does not seem to have attracted so much attention as, in my opinion, it deserves. The operation I perform is as follows:—Grasping the soft parts, so as to bring them well forward, I push the knife across from the outside and form a flap in front; this being slightly elevated, I again carry the knife in the direction which it first took, but behind the bone, and form the second flap from the posterior surface, taking care to leave it about two inches longer than the anterior: the rest of the proceedings are conducted as in the other operation. The dotted lines in the fig. 281 exhibit the comparative length of the flaps, and the seeming arch of the thigh has been accurately represented from nature. When the knife is thus placed, if the parts are as fully drawn forwards as they should be, they give this appearance of distortion, but the sketch was purposely taken in this stage of the operation with the object of illustrating this feature, and the manner in which the operator may employ his left hand when he stands on the left side of the limb about to be removed. If an operation of this kind is done towards the lower part of the thigh, it is impossible to make the anterior flap sufficiently broad unless the skin and other textures are well elevated before the knife is applied.

A moment's reflection on the anatomy of the thigh will be sufficient to convince any one of the greater tendency to shortening of the muscles on its posterior surface than on the anterior: here, with the exception perhaps of the sartorius, which, however, will not be in the anterior flap if the amputation is low down, the only muscle likely to retract much is the rectus, but it lies so close to the bone, and, moreover, its fibres are so peculiarly arranged, that its sphere of contraction
is but limited, when compared with that of those on the opposite side, where the semi-membranous, semi-tendinous, and biceps, with part of the adductor magnus, have so much scope, and are so far separated from the femur, that it would not, judging from contractions only, be unreasonable to anticipate very considerable retraction. On the living body this actually occurs, and whatever operation is performed, unless some provision is made on this account, so that at first the parts behind shall be longer than those in front, the stump after a time will never look well. Figure 282, taken from a stump made in this way by my colleague, Mr. Partridge, shows an ample cushion on all sides, without that prominence in front, formed by the end of the bone, such as is not frequently seen in stumps in this part of the limb.

During the latter years of my practice I have almost invariably given preference to this mode of operating; it answers well for all parts of the thigh, and there is as little trouble in the after-dressing as can possibly be imagined. In many cases I have not deemed it necessary to disturb the first dressings for eight days or more; and straps and bandages, although used for form's sake, might have been altogether dispensed with.

The femur is covered with such a mass of soft textures on its whole circumference, that, as I have already remarked with reference to amputations in the arm, the flaps may be taken from any opposite aspects, and I have frequently made them partly from the sides, and partly from before and behind. Sometimes, as has actually occurred, it may be deemed requisite to have only one flap, and that may be taken from any side which is free from disease or injury. The late Dr. Little, of the Sligo County Hospital, in one instance preserved a large single flap from behind,—the wound and cicatrix being thus, in some respects, like those after the single flap below the knee. Here, possibly, as Dr. Little imagined, there may be an advantage in the cicatrix being in front of the bone, and thus less exposed to pressure whilst in the socket of a wooden leg. After making such a flap I should cut away a considerable portion of the great sciatic nerve, so that it might not by any chance be brought to lie against the divided surface of the femur.

I need scarcely add, that circular operations may be performed on any part of the lower limb; I shall not, however, describe any of them in particular, but will refer the reader to the introductory Chapter on Amputation, especially to that part where this mode of procedure is described. Although it is my opinion that casualties must follow circular operations more frequently in this extremity than those by flap, I feel bound to say that I have seen stumps of an admirable kind after
the circular mode, both in the leg and thigh. Undoubtedly the proper period to judge of the excellence of a stump is after the lapse of months or years.

I recommend the outside of the limb as being the best to stand upon in amputation of the thigh, for if the operation is to be done in its upper third, with anterior and posterior flaps, it will be found that if the knife is passed from within outwards, the position of the other thigh will make it difficult to depress the hand sufficiently to enable the operator to elevate the point over the front of the bone; in short, he will discover that all the movements of his right hand will be very much cramped if he places himself between the patient's legs, or if, for example, in amputating in the upper part of the right thigh, he places himself on the patient's left side, he will find that what between the difficulty already referred to, and having to stretch across the patient's body, the whole proceedings are both troublesome and awkward.

In any of these operations the superficial femoral artery will first demand attention as soon as the part is removed. The vessel is never difficult to discover, but sometimes, particularly when the transfixion is from the outside it will be found split for an inch or more. In such a case, as well as when the artery is cut almost directly across, it must be cautiously separated from the vein with the points of the forceps, and slightly drawn out of its sheath ere the ligature is applied. The anastomotica magna may require ligature in the lower third of the thigh, but in general the main vessel is either cut across or tied above this branch. Higher up the branches of the deep femoral may require three or four additional ligatures: but it is difficult to say how many may be necessary, for I have seen instances where even the main vessel did not bleed (cases of gangrene), and most practitioners of experience must have seen occasional examples where one ligature was sufficient, whilst in others eight, ten, or a dozen have proved not more than enough. In the upper part of the thigh venous hemorrhage will often cause annoyance, but it usually ceases as soon as the pressure in the groin is taken off; and invariably does so when the flaps are laid together. The point of the finger will here also (as in the leg) be of service for a time.

Amputation at the hip-joint has now been so frequently performed, that the surgeon needs no other justification for resorting to it than the urgency of the case; and although no reasonable practitioner would ever attempt it except as a last resource, it is somewhat satisfactory to know, that with all the disadvantages under which it has been performed, particularly in military practice, and notwithstanding the fearful shock which must of necessity attend such an extensive mutilation, the success of the operation has probably been such that one patient out of every three on whom it has been performed has been saved. It is difficult, however, to collect the proper data for the statistics of this operation, but I believe I am within the mark in the above statement. During my residence in Edinburgh the operation was done four times, twice by Mr. Liston, and as often by Mr. Syme:
all the patients died, although one of the latter gentleman’s cases may actually be deemed to have succeeded, for the wound was entirely healed, when, unfortunately, effusion on the peritoneal cavity caused death within eight weeks after the operation. Mr. Syme has since had a case where he successfully removed a stump of the thigh at the articulation; Mr. Tatum, of St. George’s Hospital, has had a successful case also; and among modern instances, I may mention one by Mr. Sands Cox, of Birmingham, who published an interesting paper on the subject in 1845, and a still more remarkable case by Mr. Gamgee of the same town, who has written a valuable memoir on the operation. Much further interesting information on this subject has been furnished by American surgeons resulting from recent wars in the States, and a reference to the cases which have been so admirably recorded, has strengthened an opinion which I have long entertained, that many amputations have been performed at the hip-joint when a less formidable proceeding below or through the trochanters would have sufficed.

Fewer methods of operating on this joint have been proposed than on the shoulder, yet there is no lack of choice here either, for fifteen at least have been described. The remarks which have been made with reference to amputation at the shoulder-joint, p. 297, are equally applicable here: any one familiar with anatomy, and possessing a moderate share of dexterity with the knife, may without much difficulty disarticulate the head of the bone, either by a circular or flap incision, and whether, in following the latter method, transfixion is resorted to or the textures are cut from without towards the joint: neither does it seem of much consequence from which surface a flap is left longest, nor whether, indeed, the stump is formed of one or two.

Most surgeons have preferred the flap operation in this situation, and I am so inclined, although circumstances might necessitate certain modifications, which I shall refer to after describing the proceedings. Previous to the operation, every arrangement should be made regarding assistants, instruments and other appurtenances, and nothing should be left to chance on such a momentous occasion. The table should be stout, of a convenient height, not so broad as to prevent the surgeon and assistants being in close contact with the patient, and a folded blanket with a couple of pillows should be on its upper surface. The patient’s breech should be brought close to the margin of the table, and the sound limb should be fastened to one of its legs. An assistant should stand immediately behind the surgeon, whose chief duty will be to raise the first flap and compress the femoral artery; another should stand opposite to hold the pelvis steady, and assist in keeping the patient’s body from slipping; a third may also be useful at the shoulders to aid in this, as, from so much of the body being beyond the table, and perhaps also from the mode of operating, there is a chance of the pelvis falling over the margin: a fourth should have the limb intrusted to his care, and he, with the other who has charge of the artery, should clearly understand the intended movements of the surgeon, as the immediate and satisfactory accomplishment of the
operation depends much on the simultaneous movements of the whole three. If the circumstances are favourable, and the arrangements well concerted, the whole proceedings as regards removal of the limb, may be gone over in so brief a period, that the term "simultaneous" may be used with propriety. On the dead subject the operation can be done in twelve or twenty seconds, and it may, as I have seen, be accomplished with equal celerity on the living. The surgeon, standing on the outside of the limb, should insert the point of a long knife about midway between the anterior superior spinous process of the ilium and trochanter major, keeping it rather nearer the former than the latter; he should then run it across the front of the neck of the bone, and push it through the skin on the opposite side, about two or three inches from the anus; next, he should cut downwards and forwards, so as to make a flap from the anterior of the thigh, about five or six inches in length. When the blade is entered, the limb should be held up, and even slightly bent at the joint; the instrument will then pass along more readily than if all the textures were thrown on the stretch; moreover, there is greater certainty of passing it behind the main vessels, and even dividing some of the fibres, if not the whole, of the iliacus internus and psoas muscles. As the knife is carried downwards, the assistant, who stands nearer the patient's trunk than does the operator, should slip his fingers into the wound and carry them across to grasp the femoral artery between them and the thumb: this he may do from the inside or outside at will, and with the right or left hand, as may be most convenient, the same

Fig. 283.

grasp enabling him to raise the flap as soon as it is completed. The right hand is represented in fig. 283, which exhibits part of the operation on the left hip, but some might prefer the other hand, although I should myself put more reliance in the grasp of the right. The flap being raised, as here exhibited, the point of the knife should then be struck against the head of the bone, so as to
divide the anterior part of the capsular ligament and any textures in this situation which may not have been included in the flap. To facilitate this part of the operation, the knee should be forcibly depressed by the assistant who holds it; the head of the bone will thus be caused to start from its socket, and if the round ligament is not ruptured by the force, a slight touch with the edge of the knife will cause it to give way. At this period, depression being no longer required, the assistant should bring the head of the femur a little forwards, to allow the knife to be slipped over and behind it, and when it is in the position represented in the design, it should then be carried downwards and backwards, in the course of the dark line, so as to form a flap somewhat longer than that in front, the last cut in the skin completing the separation of the limb.

By means of the fingers of assistants (one or two more than those referred to may be of service) and the application of sponges, the bleeding may in some degree be restrained until ligatures are applied. Should the vessels seem large on the posterior flap, it will be best to secure them first, and then the superficial femoral and such other branches as may require ligature in the front flap should be attended to. If, however, there is any fear of the main vessel eluding the grasp of the assistant, there will be greater safety in tying it first. If, in making the anterior flap, the knife is kept close to the femur for some way down, the superficial femoral will not be divided until the incision is nearly completed, and this branch with those of the profunda may all be sufficiently compressed whilst the hand is used in the manner above described.

Delpech, Larrey, and others recommended ligature of the femoral artery as a preliminary step, but it seems unnecessary, and the proceeding has been rarely resorted to. Pressure with the thumbs on the brim of the pelvis has also been recommended; but as there can be no bleeding of any consequence until the main vessel is cut across, and as it is quite possible for the assistant to have his fingers behind it, as the surgeon cuts towards the surface, this preliminary pressure is not required: should the assistant, however, be unable to squeeze the flap sufficiently tight, he ought at once to apply pressure on the common femoral at Poupart's ligament, with the thumb of the hand which is free, or he may commit the flap to the charge of another, and apply both. When thus placed, however, they may prevent the flap being raised with the same facility as when they are absent, and it is of some consequence that the operator should see where to apply the knife when he is about to cut the capsular ligament.

I have not inculcated the necessity of introducing the point of the blade a certain number of lines distant from the spine of the ilium, nor have I been very precise as to the exact distance from the anus at which it should protrude, for I believe that the operator, instead of limiting himself to lines here, may actually take the freedom of inches: his object should be to make as broad a flap in front as the method by transfixion will admit of; but whether he pushes in the knife, or brings it out, an inch above or the same length below certain
given distances, seems to me of very little consequence: if he begins low down, he has to cut so much deeper, as it were, ere he reaches the capsule, and if this is a disadvantage, it is, perhaps, compensated by the wound on and near the surface being a little further from the trunk: if he introduces the point much behind the tensor vaginae femoris, he cannot with safety carry it so near the anus as if it were pushed in front of that muscle, and so what he strives for on one side is lost on the other.

Next to having command of the vessels, the management of the thigh may be deemed the most important part of the assistant's duties. If he to whom this task is allotted does not depress forcibly, and then raise the head of the bone, as has been directed, the disarticulation can never be easily and rapidly accomplished: besides, to do his work well, he should be careful when the surgeon is forming the posterior flap, not to abduct the thigh, or allow it to be turned forward on its own axis, as the knife is thus apt to get between the head of the bone and the trochanter, so that its progress is arrested. I have frequently seen this occur on the subject, and the artist has been careful in showing the limb in a proper position to obviate this difficulty. It is evident, however, that these manoeuvres with the femur cannot be practised on all occasions, as, for example, in gun-shot fracture of the neck of the bone, and the operator must therefore do the best he can, under the circumstances, in disarticulating. In such a case, the knife, after the formation of the first flap, might perhaps be insinuated between the fragments, although probably this plan would not succeed, as I have, in fractures in other parts requiring amputation, known its progress arrested or impeded by a small fragment or splinter: if the circumstances did not seem favourable for such a proceeding, the head of the bone might be dissected out, and the blade then placed behind it; but I should feel most inclined under the circumstances to make the posterior flap immediately after the first is formed, by transfixing a second time, as in the amputation of the thigh with anterior and posterior flaps, and then apply the saw above the seat of fracture, if that were possible: if this could not be done I would use it at any other convenient part, and then with a scalpel or bistoury cut away the remainder of the bone. It is possible that in such a case (indeed, I have seen it on the living body) the femur might separate at the seat of fracture after division of the soft parts, and in that event the end of the upper fragment would require to be smoothed, or perhaps its entire removal might be necessary. Here, however, as indicated in some previous remarks, and particularly if the capsule is not opened, I believe that the surgeon would do best by leaving the head of the bone in its socket.

If it seemed needful in consequence of the capsule being opened or the bone shattered by injury, the end of the upper portion might be seized by the left hand, or with the lion forceps, and turned in the requisite directions to expedite the application of the knife to the capsule and round ligament, when a slight twist will cause disarticulation.
Drawing 284 is from a cast kindly forwarded to me by Dr. Handyside of Edinburgh, who successfully performed this operation in the Royal Infirmary of that city, in the summer of 1843. The proceedings were conducted nearly in the manner above directed, and the cast was taken in the third month afterwards.

Fig. 284.

Since the last edition of this work there has been almost every imaginable variety in the modes of performing amputation in the lower extremity. Besides those referred to in this chapter, I may especially refer to the practice of Mr. Tcale. If I mistake not, more has been done in accordance with his views in this member than in the upper, and a front flap in leg and thigh seems now to be in great favour with many practitioners. To such views I have no special objections, and the selection by the surgeon may be left open to suit circumstances, as with the upper extremity.
PART IV.

OF THE HEAD AND NECK.

CHAPTER I.

SURGERY OF THE HEAD AND NECK.

The surgery of these regions may truly be held to be of particular interest. In various localities the surgeon can apply his art without a trace of his interference being left, and although this may be said of him here also, there are many instances wherein his skill with the knife is needed, and where, by tact on his part, very great and conspicuous deformity may be removed with the smallest imaginable trace of his services having been required. These observations apply especially in instances of malformation about the mouth, and to those examples of tumours on the face connected with the jaws which so frequently demand the best powers of the surgeon. But irrespective of operative interference, the surgeon's skill is so frequently tested in the treatment of diseases in these parts, that there is perhaps no region of the body which possesses so much interest in his estimation.

Those departments of surgery which are called "special," are, among the strictly professional, chiefly limited to these regions. The oculist, the aurist, and the dentist have their occupations here; and without venturing to discuss the relative merits of the different practitioners, either with regard to each other or to the surgeon properly so called, I believe it sufficient for my present purposes if I state my conviction that he who is best grounded in the general principles of Physic and Surgery, is likely to be the most efficient man in "special" practice here, and most likely to take high rank as a medical man.

It would not accord with the purposes of this work if I were to enter into minute details regarding the diseases of the head and neck. As already stated in the preface, it is not my intention to write regarding all that pertains to surgery: such knowledge may be said to be embodied in the curriculum of medical education, and this volume professes to refer chiefly to the "special" department of Surgery, which in itself cannot be said to have a scientific basis irrespective of the additional knowledge above implied.

Dislocations are comparatively rare in these regions. They happen occasionally at the articulation of the lower jaw with the cranium, and perhaps more frequently in the cervical portion of the spinal column. But even in the latter place they are not common, and the mere luxa-
tion rarely constitutes the chief feature,—the injury to the spinal cord being that which principally attracts attention. Examples of luxations in these different localities, and of their effects, will be given in a future chapter especially devoted to the subject.

The above remarks apply with equal force to many of the fractures in these parts of the body. The bones of the face, such as the nasal, malar, or maxillary, may suffer this injury without any parts of greater importance being implicated; but in the cranium and spine the effects upon the brain or spinal cord will chiefly demand the surgeon's notice.

Generally a fracture is of more importance in any part of the body than a luxation, and the maxim holds in these regions also. Yet in the spine, a luxation may be deemed in all respects as hazardous—if not more so, by permitting greater displacement. Fracture of the cranium is justly deemed a very serious injury, yet in itself it is perhaps much less so than many instances of fracture in the extremities; but usually, from such fractures being accompanied with some lesions of the brain, functional or physical, or of membranes, an amount of danger accompanies them, such as is not expected in fractures in any other region.

Fractures of the cervical portion of the spinal column rarely call forth the zeal or speculation of the surgeon, for they are usually so palpable in their nature and effects, as to leave little room for conjecture, and equally little for consideration as to the best means of treatment; but fractures of the cranium are often accompanied with complications which greatly interest the surgeon, and on the just discrimination of which some important questions of practice are dependent. It may indeed be said that some of the highest attributes of mental surgery are required for the judicious management of many of these cases. Possibly, as civilization advances, such injuries may be less common than they once were; whether this be so or not, it must be allowed that special treatment is much less frequently resorted to than in former times; and with regard to the time-honoured operation of tracpanning, it is seldom indeed that the modern surgeon resorts to it. But due notice will be taken of such matters in a future chapter.

Many of the diseases of the scalp belong as much to the province of the physician as the surgeon, and need not call forth much comment here. Whilst I place much reliance on the just exhibition of internal remedies in many such cases, I think it right to state my strong conviction that without much attention to local applications, and above all cleanliness, the influence of internal medicines will be of little avail. The scabby concretions which so frequently accumulate in some of these affections, are best got rid of by poultices, and perhaps most easily kept away thereafter by soap and water, although possibly for the cure various local stimulants and astringents may be required, in conjunction, of course, with the constitutional means above referred to.

There is no cutaneous tissue in the body so subject to the formation of tumours as the scalp, and more of such growths are met with in this than in any other region. There are few kinds of tumours which may not be met with here, but generally those of the encysted kind are of
Surgery of the Head and Neck.

The most frequent occurrence. Of these there are the usual varieties both as regards size, thickness, and the contents of the sac. It is rare to see more than a single cyst in other regions of the body, but not only may there be many—dozens, perhaps, scattered over the scalp singly, but there may actually be groups of half a dozen together, which, in reality, though distinct from each other, appear on external examination as a single mass. Vascular tumours, presenting the usual characters of naevi and aneurisms by anastomosis, are of common occurrence in most parts of the head, face, and neck. These are generally superficial, and often tax the ingenuity of the surgeon as to the manner in which he may best treat them without leaving conspicuous marks. The chapter on this subject in the first section of the volume will afford further information regarding cases of this disease in these regions.

The bones of the cranium are subject to those diseases which are met with elsewhere in osseous structure, but such cases require little special notice here. In most other regions, the bone itself when affected constitutes, as it were, the principal seat of the disease, and while this may be admitted in the head also, yet the contiguity of the brain and its membranes cannot be overlooked, and on this account the danger of disease of bone here may be deemed greater than elsewhere. It may be admitted as remarkable, however, that caries and necrosis to a great extent may go on in the upper part of the cranium without the slightest indication of internal mischief. In certain instances of disease of bone in this region, the surgeon can interfere with active local measures in the most efficient manner, as is frequently exemplified by the manner in which he treats abscess, caries, necrosis, and various tumours of bone in the face, yet in some he must use great caution, as when there may be disease of the external auditory passage, or of the cells of the mastoid process. Due notice will be taken of the most of such cases in future chapters.

Diseases of joints are of rare occurrence in this portion of the body. In that between the lower jaw and cranium I have never met with a single instance of serious mischief. I have seen various examples in females, about the age of twenty, of painful jerking in one or both of these joints, as if a luxation were about to take place, and in such patients I have found that limiting the movements of the lower jaw by an elastic bandage, and giving tonic remedies, especially such as are likely to obviate hysteria, have proved very successful. It may not be easy on all occasions to distinguish between disease of the articulations in the neck and of the bones. Perhaps it is of no great moment, as the practice in the one case is equally eligible in the other, but that joints here are specially diseased there can be no doubt, both from what we see during life, as well as on inspection of the dead body. The usual results are observable here as in other localities, but the most interesting and important feature of all such cases has reference to the effect of the disease on the spinal column. Some particular reference to this subject will be found in a future chapter.

Many of the diseased conditions of the eyelid, orbit, and eyeball,
are such as can be readily and perhaps best appreciated by one conversant with the principles of surgery, and partly on this account, as well as because ophthalmic surgery has in a manner been held as a distinct branch of surgery, I have not thought it requisite to dwell particularly upon diseases of the eyeball, especially as regards its functions. Many of those alluded to are so plainly the result of physical derangement, that any one who professes an acquaintance with pathology may readily form an opinion about such cases. In other instances where function is interfered with without any perceptible appreciable cause, the practitioner can only take his position on the speculative view, that in some way or other the patient is out of health, as is evinced by the state of his vision. In recent times the ophthalmoscope has been found of much value in giving precision to the diagnosis of many cases which formerly were shrouded in obscurity. Depletion in its various forms, alteratives and tonics, are all freely used in such cases, in accordance with circumstances, and often with most marked effect; but the practice is so analogous to that which may seem requisite in most other examples of local disease, that special notice of it does not seem requisite. From the bulk of writings on Ophthalmic Surgery, and the circumstance of its being deemed a "special" department, there is a very prevalent impression that the surgery of the eye is materially different from that of any other part or organ of the body. While there is some truth in this view, from the peculiarity of textures and function, the same might be said of most regions, organs, or tissues in the frame. It seems to me that the well-educated medical man should be as readily able to appreciate disease in one organ or tissue as in another. I presume, therefore, that any one acquainted with the nature and history of inflammation and its consequences, may deal with such conditions in the eyeball. Inflammation, whether occurring on the surface of the eye, or in the interior, in a constitution without any marked peculiarity, or in a strumous, gouty, or syphilitic state, whether characterized by simple increase of vascularity and pain, by exudation of lymph, or purulent secretion, may always be readily appreciated by those conversant with the principles of surgery, and while I do not mean to undervalue this department, I feel that in such a work as this, there is no need for dwelling specially on what is usually styled Ophthalmic Surgery. In fact, many of the subjects aboved referred to, might with as much propriety be called Ophthalmic Medicine, and I must refer to a future chapter for a description of some of the special duties of the surgeon, as regards his treatment of diseases in the eyeball and its appendages. There are many diseases of great interest to the surgeon connected with the nose and nostrils, but none of these require more than a passing notice here, as they are particularly considered in future pages. The surgery of the lips, too, is mostly comprised in the chapter on the operations on these parts, and therefore needs no special comments here; and the same may be said regarding the surgery of the tongue, throat, ear, palate, and mouth. Whatever may be deemed deficient in the chapter devoted to such subjects, may in part be acquired in the
introductory section of the volume, but must chiefly be made up by that knowledge of pathology and medicine which every well educated surgeon is presumed to possess.

There are few departments of operative surgery wherein so much has been done during the last forty years, as in connexion with diseases of the jaws. Such diseases are in most respects analogous to those which are found in the bones in other parts of the body. Yet they are modified by locality and circumstances, and the operations for their removal require so much more skill and ingenuity than is needful in most other regions where the surgeon can resort to operative treatment, that they are often deemed of especial interest. Possibly one great reason for this may be, that many of these operations are comparatively of modern date, and, it may be added, of such rare occurrence, that the experience of any single surgeon is so limited, that he is naturally desirous of becoming acquainted with whatever is done in such cases. The chapter on the operations on the jaws, in a subsequent part of this section, will be found to contain practical descriptions of most of the diseases for which surgical interference is required; and while I deem it presumptuous to pass an opinion upon the relative merits of the different sections of this book, I should fain hope that a perusal of the chapter alluded to, as well as of various others in this section, will prove of some value to those who may have cases such as those referred to under their particular notice or treatment.

CHAPTER II.

DISLOCATIONS. FRACTURES. OPERATIONS ON THE SCALP AND CRANIUM.

Dislocations in this region are few and of rare occurrence. The cervical vertebrae are occasionally displaced, either as the result of accident or disease. When the former happens it is customary to suppose that the spinal marrow is so injured that immediate death is the result, especially if the injury is above the origin of the phrenic nerve. I have not myself seen any case of this kind, but I believe that there are few in the profession who doubt the truth of the current doctrine: it has been asserted, however, that such displacements may be treated like luxations in the extremities—that is, by extension and counter-extension, and cases have been recorded in modern journals. The practice which has been proposed in such instances is not so novel as some people imagine. Heister states that "what is vulgarly called a broken neck is generally no more than a luxation, though sometimes the vertebrae are fractured. If life should remain after such a luxation, which very rarely happens, the patient's head is commonly distorted, with his chin close down to his breast, so that he can neither swallow anything, nor speak, nor even move any part that
is below his neck; therefore, if speedy assistance be not had, death ensues from the compressure or hurt of the medulla.

"But to repulse this unwelcome messenger, the patient is to be immediately laid flat upon the ground or floor; then the surgeon kneeling down, with his knees against the patient's shoulders, is to bring them together so as to contain the patient's neck between them: this done, he quickly lays hold of the patient's head with both his hands, strongly pulling or extending it, he gently moves it from one side to the other, till he finds, by a noise, the natural position of the neck, and the remission of the symptoms, that the dislocation is properly reduced."

That the neck may be straightened in this way I believe, but I should imagine that the injury to the spinal marrow would be such that this "unwelcome messenger" would keep his place. Heister is certainly a very different authority on professional matters than Rabelais, yet by the above account one is forcibly reminded of the exploit of Panurge in replacing the severed head of his friend Episthenon.

In the upper part of the neck, where authentic and accredited cases have been observed by professional men, immediate death has ensued in instances of displacement. Thus, a person's head has suddenly dropped forward, and life has become extinct instantaneously: on dissection, it has been found that the atlas and the head have been permitted to fall, in consequence of the rupture of the transverse or cruciform ligament, the odontoid process remaining erect; the medulla oblongata has been in a manner transfixed by it—at all events, the contusion has been such as to cause the sudden event. Sometimes chronic inflammation has been previously known to have been present in certain of these cases; on other occasions, no suspicion of disease has been entertained, and there are good reasons for supposing that, when the parts are perfectly healthy, a vast force is required to cause such displacements. It is imagined by many that in persons who suffer the extreme penalty of the law by hanging, the cervical vertebrae are broken or dislocated; but though this doubtless happens on some occasions, as is known from good authorities, Dr. Houston of Dublin has related several dissections of such individuals, where no perceptible injury had been inflicted either on the spine or its contents. It is well known, on the other hand, that a slow process of displacement and distortion may go on in this region, and yet the medulla oblongata and the spinal marrow below will retain all their functions: the changes go on so gradually that these parts become accustomed to their altered shapes, and the organs below remain in vigorous condition. Similar facts are often observable in the inferior portion of the spine, and in a future page I shall return to this subject.

Some years ago I met with two instances of injury of the upper part of the spinal marrow, which may be referred to here with advantage. One occurred in a middle-aged healthy man who fell head foremost down a very narrow staircase, so that the weight of his body caused his head to be twisted towards his chest. He was picked up imme-
diately, and I saw him with Mr. Cross, of Leicester Square, within a few hours after. He had lost all power in his lower extremities and abdominal parietes, but could still move his arms, though imperfectly, and could breathe with tolerable facility, chiefly by means of the diaphragm. He was free from all other serious injury, and perfectly sensible. His mental anxiety was considerable, and, as in the course of hours the difficulty of breathing became greater, and his power over the arms less, his distress was extreme. He frequently deplored his condition, having no sensation in, nor power to move, either hand or foot, while quite conscious of all that was going on around. Gradually the difficulty of breathing increased; as it did so, he became unconscious in proportion, and died on the fourth day seemingly and literally from the want of power to breathe. On examination after death, partial fracture and luxation were detected between the third and fourth cervical vertebrae, with softening of the spinal marrow upwards and down,—this condition resulting, doubtless, from the inflammation which followed the first injury inflicted during the fall. The other case was one which I saw with Mr. Lavies, of Great George Street, Westminster. The patient, aged thirty-six, had long suffered from symptoms of disease of the cervical portion of the spine, and when I saw him first a large abscess had formed in the side of the neck and behind the pharynx: when this was evacuated, the bodies of several of the vertebrae could be felt bare. The patient, although greatly exhausted by inflammation and suppuration, was in possession of all his mental faculties, and could move his limbs and every part of his body, as if in health, excepting that when he desired to turn his head he was obliged to put his hands up and hold it steady until the body was moved round in the direction he wished. A few weeks after the abscess was opened, he was making some unusual movement in bed, when his head suddenly fell a little forwards, and immediately thereafter he had complete paralysis of the upper and lower extremities. He retained his consciousness for some hours as perfectly as in the case above alluded to, but gradually difficulty of breathing became extreme, and he died within four days quite exhausted. Here we found, on dissection, that a separation, or luxation, had taken place between the third and fourth cervical vertebrae, and that the injury to the spinal cord at the time, and the subsequent pressure from the displacement, had induced softening of the medullary substance in the immediate vicinity. I may here refer to some additional observations on injuries of the spine in the section on the chest.

Fractures are not uncommon in this region of the body: they probably happen as frequently as dislocations, and doubtless the two are often combined; but here, as with the luxations, the effect on the bone is not of such consequence as that on the contents of the canal.

Dislocation of the lower jaw occasionally happens, and in certain individuals the articulations seem so lax that the condyles are remarkably prone to slip forwards, which is the only course they can take. One articulation or both may suffer at the same time, and in either case the effect is, that the patient cannot shut the mouth. It usually
is the result of gaping very wide,—a yawn has been known to produce it; and if any force is applied against the chin when the mouth is even moderately open, the condyles are very likely to start forward. The following drawing (fig. 285) shows the appearance of the features under such circumstances, and the condyle of the maxilla may be supposed resting in front of the articular surface on the temporal bone. Under such circumstances the countenance wears a singular aspect. Some time ago a gentleman, attired in a morning gown, and with his dress otherwise in considerable dishabille, entered my consulting-room with his mouth open, and such an expression of face, that my first idea was that a lunatic was my visitor; but I soon found that he had dislocation of one condyle of his lower jaw, and that his haggard appearance resulted from a night’s suffering on this account, and from various attempts which had been made without success to reduce the luxation.

This condition may be easily remedied by passing the thumb into the mouth, and pressing the bone downwards and backwards by pushing against the molar teeth. One or both thumbs may be used as may be required, and it is recommended to cover each with a towel in case of injury from the sudden closure of the jaws. I have generally noticed that little force is required on these occasions, and have never observed that snap of the jaw which is supposed to endanger the operator’s digits.

I have met with several instances, in females about twenty years of age, disposed to hysteria, of a peculiar cracking in the joint attended with some pain, and a feeling as if luxation were about to occur. In these examples I have found an elastic bandage give support and prevent the mouth being opened wide, and a course of tonics, especially of the preparations of iron, of much service.

The lower jaw is frequently broken, and the injury may be produced in various ways, though in all the violence must be very considerable. A fall on the part—a gun-shot—a blow with a stick or with the fist—a kick from a horse, and such like force, will produce it; and the accident may be accompanied with a wound in the cheek or not:—in any way it must in some respects be deemed a compound fracture; for as it is seldom that the fissure does not extend into the

Fig. 285.
mouth, it may here be considered as being exposed to the air. The latter circumstance seems of little consequence here, however, for it rarely happens that serious results, as regards the bone or its coverings, occur in such cases. The accompanying drawing (fig. 286) shows a fissure in a part of the bone where it is very common, viz., in the mental region; sometimes it is further back, and occasionally a separation takes place as here represented, and towards the angle of the bone at the same time. The condyles are broken off in this instance,—a most unusual occurrence, I believe,—but the patient, from whose body I took the preparation after death, had a fall from a great height, which caused most extensive injury. The symphysis is no unusual seat of fissure in young persons.

It is seldom that there is any difficulty in detecting the nature of such a case: the history of the injury,—the pain on moving the jaw, the crepitus, and the irregularity in the teeth and alveoli, usually at once indicate what is wrong: nor is there much difficulty in the treatment, for whatever will suffice to keep the fragments moderately steady will fulfil all that can be desired. The method which I have usually followed has been to shape two narrow wedges of cork about an inch and a half long, a quarter thick at the base, and sloping away to a point, one of which has been placed on each side between the teeth, and then I have affixed a wetted and softened piece of pasteboard on the chin, which has next been drawn tightly up by means of a bandage carried from this part over the crown of the head: as the pasteboard has got dry, a kind of mould has thus been formed on the chin, which has obstructed all future movements so long as it has been kept on. The cork wedges have insured regularity as regards the teeth, and an opening has been left between the incisors, whereby the patient has been fed upon soups and other fluid nourishment. Generally, however, the wedges have become loose, and in the course of ten or fifteen days the patients have become accustomed to restrain the movements of the part; and without taking particular pains about tightening the bandages afterwards, I have usually seen most excellent cures follow. Recently I treated a case of this kind in a boy, on whom, partly from restlessness and partly in consequence of a wound in the skin, it was impossible to adjust any apparatus in an accurate manner: the fragments, though moveable at first, soon became in a manner fixed by the surrounding inflammatory swelling, and the case went on as favourably as could have been desired. When the cork is used, and indeed under any circumstances, the patient should be enjoined to rinse the mouth frequently, and a little tincture of myrrh put into

Fig. 286.
the water may assist occasionally in keeping the gums in tolerable condition until more freedom can be taken with the parts. Various pieces of mechanism have been devised for this kind of fracture: a leather case to fit the chin and to fasten on the head by straps and buckles may be applied; a double-headed roller, having a slit in the middle to receive the chin, has been a favourite bandage. Mr. Londale invented an ingenious steel apparatus for the purpose; occasionally, if the teeth are sound and firm, they are held in proper position by turns of soft wire; but for my own part, I prefer the pasteboard, cork, and bandage above recommended, and it might be an additional advantage to moisten the latter with solution of starch, or other glutinous material used in the treatment of fractures elsewhere. In the present day the gutta-percha answers the purposes above indicated still better than the pasteboard.

Fractures of the hyoid bone occasionally occur in rough injuries about the neck, and Dr. Gibb has described, in the sixth volume of the British-American Medical and Physical Journal, a case of fracture of the thyroid cartilage: but such cases are extremely rare, and require no special rules of practice worthy of being specified here.

The nasal bones, from their exposed position, are often broken, by blows, falls, and such-like violence: from the frequency with which united fractures are met with in the dissecting-room, I imagine that such injuries occur less rarely than some suppose. Usually the confusion which accompanies such a fracture is so great, than any examination with the fingers is productive of considerable suffering; fortunately, however, there is no need to persist long in the examination, for a slight touch will detect the mobility of the parts, which is as good a criterion here as crepitus. If there is displacement, the fragments should be put in a favourable attitude; commonly this can be done on the outside, but it will possibly be necessary to introduce into the nostrils the end of a probe or director covered with lint, so as to elevate any portion that may be depressed. Afterwards the patient must be kept quiet, cold cloths should be laid on the part, and if inflammation runs high, leeches may be resorted to. There is a danger here of inflammation extending from the ethmoid bone to the dura mater, and the most serious effects may ensue. In general I do not think there is much hazard; but it behoves the practitioner to be on his guard, as it is known that the base of the cranium has sometimes been involved in the injury. Lately I had a case of fracture of the nose under my charge, which happened in a singular manner: the patient was a servant in the establishment of a dealer in bottled malt liquor: a bottle in one of the bins burst with such violence as to dash the heavy bottom against his nose, and thus cause fracture of a severe description. I watched this man with great care. About eight days after the accident he began to complain of deep-seated pain in the forehead: his pulse rose, his tongue became dry, and various symptoms led me to suspect internal inflammation. Immediately a dozen leeches were ordered to the forehead, a smart purge was administered, when in two days he felt quite relieved, and soon made an excellent
FRACTURES OF THE CRANIUM. CONCUSSION. 459

recovery. Here possibly these means were resorted to in good time; for one could scarcely have suspected such relief if the inflammation (supposing any to have existed) had been far advanced.

Fractures of the other bones of the face are comparatively of rare occurrence: they also are caused by blows, gunshots, kicks from men or horses, &c., and require no particular comment here. A case of this kind which I saw, was occasioned by a mass of rubbish falling on the patient's head and face; the bones were extremely shattered, the frontal bone also having suffered: death ensued on the eighth day, chiefly in consequence of severe inflammation and suppuration throughout the whole face, which had also extended within the cranium under the anterior lobes of the brain. I have recently seen an instance of fracture of the upper jaw midway between the alveoli and orbit, on one side, in a case of congenital split in the hard palate and alveoli. It occurred in a boy about puberty, and from a comparatively slight blow. This I attribute to want of support in the mesial line. The case is, in as far as I know, unique in the annals of surgery.

Fractures of the cranium are as frequent as any of those already alluded to in this part of the body, and are usually of much more serious import than any others, with the exception, perhaps, of those in the spine. The upper surface being more exposed to external violence most generally suffers; but the base of the skull is frequently the seat of such injuries. The fracture may occur immediately under the external force, or it may be directly opposite: thus, a blow on one side of the head may occasion fracture on the other, and an injury sustained on the vertex may cause fissure at the base. Sometimes there is merely a chink of slight extent, or it may run over half, or more, of the cranium: at other times there is a wide gap, occasioned either by extensive separation of the fragments,—a kind of expansion of the skull, as it were,—or by a portion being depressed: again, the solution of continuity may be in the body of a bone, or between two or more in the seat of a suture; or it may extend from one to another across the latter. Occasionally the outer table may alone be depressed, as at the frontal sinuses, or possibly into the diploe, or it may happen that the inner table gives way while the outer resists. The scalp may or may not exhibit an external wound: the dura mater may or may not be lacerated: its largest artery (middle meningeal) may or may not be torn across: the sinuses may suffer or remain entire, and the brain itself can scarcely escape from a functional and physical lesion.

The circumstance of a fracture being simple or compound (in the usual acceptance of these terms) is of little consequence here: assuredly a compound one, ceteris paribus, must be deemed the worst; but the injury done to the brain at the time of the accident, or the subsequent effects upon this organ, are what chiefly attract the especial notice and care of the practitioner. However, in the elementary and mechanical details even here, various general rules are applicable, with which the young surgeon should be familiar. First, then, it is known that such an injury cannot be sustained without a certain amount of that effect so well understood by the term concus-
sion. This state is characterized by insensibility, slow and small pulse, quiet respiration, pale and cold surface, contracted pupil, and is usually contrasted with that termed compression, which is recognized by a full pulse, though slow, loud breathing (stertorous), surface probably hot, and of usual colour, pupil dilated, retina insensible to light, and paralysis of limbs more or less distinct.

Unless the injury be very severe, the patient soon recovers from the state of concussion, and his condition comes nearer to that of health: it may happen that an excess of reaction, as it were, takes place, and inflammation within the cranium ensues. At first, the practitioner's object should be to rouse the patient from this condition: cordials, stimulants, warmth, and blood-letting are the ordinary means: the latter plan is generally resorted to at the earliest period possible, and though in so far as the mere state of the pulse goes, the method is in contradiction to the usual doctrine of not bleeding in a state of shock, I believe that in some instances it may be of the utmost value. The late Professor Reid, of St. Andrews, found that after producing concussion in a rabbit, the right auricle of the heart became unable to act in consequence of over-distension, and that the animal died under these circumstances: if, on the contrary, another was injured in a similar way, and a vein in the neck opened to lessen the quantity of blood in the vessels leading to the part, its action continued, and recovery took place. When the patient is roused, his condition must then be carefully watched, and should symptoms of over-action (inflammation) show themselves, the lancet, and other active measures for subduing this disease, must be speedily and assiduously resorted to.

In concussion, unless the injury be immediately fatal, nature seems in a manner to struggle against such an event, the patient recovers to a certain extent, and then perhaps inflammation may run its course, or possibly the rally may be complete. Not so, however, with compression: this condition may not evince itself for hours, days, or even weeks, after the injury. If the skull is fractured, and a portion of bone be driven down upon the brain, the symptoms of compression will almost invariably be coeval with the injury, and though occasionally these may go off even when there is depression, it more frequently happens that they lead on to a fatal termination, unless some interference on the part of the surgeon is successful. Sometimes in injury of the head a person seems at first to suffer from concussion: in the course of a few minutes, half an hour, an hour or more, he, as it were, recovers from the shock, but for a brief time only,—he gradually becomes insensible again, and all the symptoms of compression become more or less distinct. Such has been the history of some instances when the middle meningeal artery has been torn: the circulation, which is always languid during the state of concussion or shock, has not been sufficient to force the blood between the cranium and dura mater; but as the heart's action has become more vigorous extravasation has occurred, and the accumulation has caused compression. On other occasions, whether concussion has ever
been present or not, and either without or with fracture, in the course of a week, a fortnight, or more, compression has come on in consequence of the formation of pus within the cranium.

All these symptoms, conditions, and causes, have been made by many authors to appear very distinct in as far as language and printing are concerned, but in practice the difficulties of diagnosis are often so great, that even the most experienced surgeon will occasionally be at fault: the co-existence of concussion and compression has been especially noticed by practical men, as also the impossibility of distinguishing which of these conditions is most urgent, and there are few indeed who can congratulate themselves on their invariable accuracy in the investigation of such cases.

A fracture in the cranium is seldom difficult to detect. If the skin is entire, the swelling resulting from the contusion may prevent a very accurate diagnosis, even in an instance where there may be depression: the hard "puffy" tumour which forms on these occasions may possibly cause deception; but unless there be symptoms of compression, the surgeon may in the meantime rest satisfied, and treat the case otherwise, as reason and a moderate share of professional knowledge must indicate. He will seldom err in abstracting blood by the lancet or by leeches, and the usual antiphlogistic treatment, combined with rest and quietude, must be carefully kept in view, either to obviate or to cope with inflammation. If the scalp be opened by the injury, then there can be less trouble in detecting a fissure, more especially if there is a portion of bone depressed: the finger must be introduced into the wound, should a glance not decide; and if it should be deemed necessary to facilitate the examination, the orifice in the scalp may be enlarged with a scalpel or probe-pointed bistoury. In the instance where there is no external aperture in the scalp, should symptoms of compression supervene, or should it for other reasons be thought necessary to ascertain if fracture exists, the surgeon may be fully entitled to make an incision, and to proceed with the examination as he would in a case of compound fracture. By such a practice, it will be perceived that he violates, as it were, one of the standard rules of surgery, which incules the necessity of avoiding the exposure of the ends of fragments in cases of simple fracture; but here the circumstances are different from what obtains in other parts of the body,—it is not the compound fracture which is to be dreaded, but the injury of the contents of the cranium.

Supposing the ease to be palpably one of fracture, and even fracture with depression, the practice need not differ from that which I have already alluded to, unless peculiar symptoms are evinced; but the necessity for watching the patient should not be forgotten; if there are any occasions on which additional care on the part of the practitioner is necessary, this is an instance; and should symptoms either of compression or of inflammation exhibit themselves, then he must resort to the appropriate modes of treatment. It sometimes happens that, combined with an open wound in the scalp, there is a comminuted fracture, and several portions of bone lie almost loose on the
surface: here, I think, there need not be a doubt about the propriety of removing these fragments, as they can only act as sources of irritation, which may produce dangerous consequences on the dura mater. I should consider it highly culpable to leave fragments in this condition; and should scarcely have urged the necessity for the practice, had I not seen them allowed to remain in such a state, and thus, in all likelihood, promote the fatal event which ensued.

If there be a wound in the integument, it must be treated as one would be in another part; it may be stitched, strapped, or poulticed, according to circumstances. Whether there is an opening or not, it is an almost invariable custom to apply cold; but should suppuration threaten externally, I should often prefer a poultice, under the impression that this process would counteract any expected excess of vascular action within. Undoubtedly, according to established custom, I should always apply cold at first in these cases; but I should certainly place most of my faith in other measures, most likely, in my opinion, to avert or subdue deep-seated inflammation. In all severe injuries of the scalp or cranium, one of the first measures should be to remove the hair around, and in general it will be best at once to have the whole head shaved.

In a case of compound fracture with depression, although symptoms of compression should not be present, I should deem it proper practice to elevate the piece of bone, provided that could be done without causing additional injury: there is no urgent necessity for this, however, unless the fragment be fairly driven into the brain, and it would only be in the event of compression occurring, whether in cases of compound or of simple fracture with slight depression, that I should make incisions to elevate the sunken bone.

If a person had received a blow on the temple, and if the symptoms indicated effusion of blood from the meningeal artery, the surgeon should not hesitate to perforate the cranium with a trephine, over the supposed collection; and in the event of compression coming on in the course of a number of days, and when suppuration might be suspected, the same method might be adopted. Here, however, it might be difficult to determine on the part to which the trephine should be applied. Where blood has been suspected, I have seen great hesitation on the latter point, and so also there may be in the supposition of an abscess being present. In the latter case, the wound on the surface would probably be selected, especially if the bone around seemed diminished in its vascularity, or altogether deprived of circulation.

When a depressed portion of bone has to be raised, it is almost impossible to apply an instrument for the purpose with proper effect, without making an aperture in the cranium: if a foreign body, such as a musket-bullet or other similar missile, is the cause of compression, it may be necessary to make an opening to permit its extraction, and the same is required when blood or matter must be evacuated. A circular saw is generally used on these occasions; it is technically called a trepan or trephine, and the operation
is named trepanning or trephining. The trephine put into the modern surgeon's Armamentarium is similar to that represented in the next drawing; it is worked backwards and forwards by a rotary motion of the hand, but some even yet prefer the instrument of Hildanus, which is worked like the carpenter's or cooper's brace. I myself prefer the hand trephine, such as is exhibited in fig. 287, and it may be used thus: the scalp must be sufficiently opened by a $\sqrt{\phantom{1}}$, an $\mathcal{L}$, a $\mathcal{F}$.

or any other incision that may be most convenient; next a perforator should be applied to make a small hole in the external table into which the central pin of the trephine should be placed, and then by rotatory motions the teeth should be carried into the bone: the external table and the diploe may be cut with bold and free movements, but caution is requisite when the inner plate is encountered, as also in those parts of the cranium where there is no diploe, and where the thickness is irregular and uncertain: the central pin should now be drawn above the level of the serrated edge of the saw, and again by more cautious movements the vitreous table must be divided: when the incision is supposed to be nearly complete the instrument must be removed: an elevator should then be introduced so as to raise the loosened portion, and the rest of the operation may be conducted according to circumstances. When a foreign substance, blood, or matter, is sought for under the cranium, a circular piece of bone is thus removed; but in the case of depressed fracture, only a little more than a semicircular portion requires to be cut, and this, be it observed by the young student, is taken from the sound portion of the bone, not that which is depressed; for the sole object in applying the instrument in a case of this kind is, to permit the introduction of a lever to elevate the portion at fault. In such a case I have known the cutting pliers used instead, or a small saw, similar to those afterwards represented for operations on the jaws. In using the trephines commonly sold, it is necessary to raise them from the groove from time to time, so as to allow the particles of bone to be brushed away, but the blade being slit up and perforated in the manner represented in the sketch obviates this. However, towards the latter part of the proceedings it is proper to remove the teeth once or twice and to examine the fissure with the point of a probe, a slip of quill, or any other con-

---

**Fig. 287.**
venient article, so as to make sure that the dura mater is not in
danger from the skull-cap being thicker on one side of the opening
than on the other.

In the instance of fracture the operator can scarcely go wrong as to
the proper part for applying the instrument, but in other cases he
may discover that he has erred in this diagnosis, or he may then (not
finding that which he has expected) think of opening another part of
the cranium, either immediately contiguous or at a distance. Such
proceedings are now rarely ever heard of, yet, under desperate cir-
cumstances, I should consider the surgeon justified in making further
search; provided always that he has some degree of reason on his
side (such as that the patient is not actually in articulo, for I have
heard of a zealous practitioner persisting in the use of the instrument
until it was hinted that his patient was dead), and there is no lack of
authority for such a course. Two, three, and four pieces—even a
larger number—have often been removed with success; and Vander
Wiel relates an instance where the trepan was applied twenty-seven
different times with success.

Supposing that nothing is found between the cranium and dura
mater, an opening may be made into the latter membrane; for although,
in general, the case will be very hopeless in such an example, still the
mere opening in this texture will not very materially increase the
danger, while it yet affords a faint advantage.

The trepan may be applied in any part of the side or upper portion
of the cranium, and a knowledge of anatomy will indicate where the
bones are thick or the reverse, and also where the meningeal artery or
the sinuses are in danger. The latter I should imagine may always
be avoided: the former, if it is necessary to operate over its course,
may possibly be cut across, as at the side of the cranium it often runs
in a canal of bone instead of being merely in a groove: a small pin of
wood in such a case would suppress the bleeding, and any escape that
might happen ere this could be introduced, would probably be rather
an advantage than otherwise: for, generally, those who require this
operation have been in robust health previously, and (besides the pos-
tive advantage in most instances) can well sustain the loss of ten or
twenty ounces of blood, in the event of such a quantity escaping from
this source. The irregular thickness of the bones at different parts
should be remembered, and the pressure of the teeth should be made
light or heavy in proportion. At the frontal sinuses Sir Charles Bell
recommended that the inner table shall be taken out with a smaller-
headed trephine than that which has been first applied: the large
external opening permitting the entire circumference of the cutting
margin of the latter instrument being placed directly on the surface
within. Such an operation must, however, be rarely required in this
situation.

The wound here must be treated according to circumstances. Gene-
rally union by the first intention is promoted, but if clots of blood or
other matter be expected to be discharged, the surface should be kept
open, and water dressing will be most advantageous. When the wound
It required this considerable long should absorption made again puncture this presumed necessity here shall passes blow. boy diploma of infants, that without the cerebri) scar, aperture is partly by the formation of bone within the circumference, that ultimately nothing of the kind is required. If fungus (fungus cerebri) should follow the operation, pressure should first be resorted to; if this does not succeed, then stypics, caustics, ligature, or removal by the knife may be tried, one after the other, as the conditions may indicate.

My limits will not permit of more than the above brief sketch of these most interesting subjects, and having others of equal importance, as regards the design of this work, still to refer to, I shall not dwell longer upon them, but will only state further, as has already been done so frequently regarding other matters, that the treatment of such cases must be conducted on those general principles of practice which any individual with a diploma is presumed to possess. To say the truth, as I read over the last few pages, I feel as if they refer to things of a bygone date, for what with changes in surgery as regards fractures of the cranium,—particularly giving up the free use of the trephine, and possibly also that broken heads are of rarer occurrence than in former times in civil life,—a long lifetime in surgery may be spent without a necessity arising for much consideration of some these doctrines.

Occasionally injuries of the scalp, with or without fracture of the bones, are followed by remarkable effusions of blood. In new-born infants, on whom instruments have been used, such collections are sometimes observed. On grown-up persons I have seen some examples of large bloody swellings succeeding to blows. In one instance I made an opening in the skin of the brow in an old woman (who had fallen downstairs and suffered great contusion of the scalp), and evacuated more than eight ounces of clotted blood: in another, a boy about twelve, a large swelling formed suddenly over the temple after falling on the part: here about ten ounces of fluid blood escaped through a small lancet puncture which was made, and then I applied compresses and a bandage, but in two days the swelling was nearly as large as ever: again I made a puncture and reapplied the pressure, which then had the desired effect. Doubtless a considerable branch of the temporal artery had been ruptured in this case, and had the second attempt with pressure not succeeded, I should in all probability have cut down upon that vessel, where it passes above the zygoma, and applied a ligature. Recently a case of large effusion under the scalp was in King's College Hospital. The patient was a boy of nine years old, and the condition resulted from a blow. It was thought that an opening would be needful, but judging from past experience I resolved to let matters alone, and trust to absorption taking place. In a few weeks, with rest and an evaporating lotion, the swelling gradually disappeared. I have seen an instance where a small aneurism by anastomosis, connected with a branch of the temporal artery, followed a blow
on the part, and I had some time ago under treatment an example of
a similar kind in the course of the occipital. It was for a pulsating
aneurismal tumour of the scalp succeeding to a wound over the occiput
that Kuhl placed ligatures on the common carotids, and I have myself
referred to an interesting example of this form of disease in the Chapter
on Anenrism by Anastomosis.

Besides the methods of abstracting blood by the lancet, already
referred to in other parts of this volume, it has been occasionally the
custom to open the temporal artery for this purpose, and it is here
that Arteriotomy (as such a proceeding is called) is usually performed.
It may be done thus: A branch being selected, the thumb or fore-
finger of the left hand should be placed upon it so as to keep the skin
steady, then the lancet, held as represented at page 249, should be
thrust into the vessel so as to cut it nearly half across in an oblique
direction: the pressure should then be taken off, and the blood per-
mitted to spring from the orifice, and when a sufficient quantity has
escapeed, a firm pad should be placed upon the wound and retained by
a bandage, drawn pretty tight round the head, which should be
allowed to remain for three or four days. Generally the anterior
branch of the temporal is selected for this proceeding, but sometimes
the posterior is most convenient, whilst on other occasions the trunk
itself is selected. In the adult the first of these commonly yields any
quantity of blood which may be desired; in a young person, however,
on whom these vessels have not attained the magnitude which they
assume in advanced years, it may be difficult to procure enough.
Sometimes it is well, when the scalp is thick, to make an incision
about half an inch long over the vessel about to be punctured, and
then introduce the lancet. The latter instrument may suffice for the
purpose, or a scalpel may be used, and then the lancet, although there
could be no difficulty in accomplishing the whole proceeding with a
sharp scalpel or bistoury.

The pressure by pad and bandage above recommended, may not on
all occasions at once arrest the flow; in such an event it is customary
to introduce the lancet again, and cut the vessel completely across, and
if this with continued pressure does not suffice, a needle and thread, in
the fashion of the twisted suture, may be used, or an incision should
be made in the seat of the puncture, and a ligature applied on the
bleeding orifice. I have known two necessary, one above, the other
below, in consequence of the free anastomoses of the vessels in this
situation. If infiltration has taken place, possibly some trouble might
be experienced in securing the artery at this part, and perhaps the
best plan would be to make an incision about an inch in length above
the root of the zygoma, over the main vessel, and apply the ligature
there. It lies so close under the skin that pulsation can easily be felt,
and it will be accompanied by one, or probably two, small veins,
which of course should be held aside. Here too I may notice that the
changes in the treatment of disease have been such in regard to the
abstraction of blood, that these remarks about this once not uncommon
operation may in a manner be deemed obsolete.
Besides the operation above alluded to, the surgeon has occasionally to make incisions, in instances of erysipelas, suppuration, and for the removal of tumours. Unless erysipelas inflammation has run on to suppuration, it is seldom that in this situation incisions are resorted to; but when pus has formed there can be no doubt about the propriety of making them. No special rules are required for the guidance of the knife here, further than those referred to in the Chapter on Abscess. The same general observations which I have made regarding the removal of tumours in the introductory portion of this work will illustrate the mode of procedure in this region. Enyestd tumours (wens, as they are commonly called) are of most frequent occurrence here; but sarcomatous growths are also occasionally met with. It is seldom that cysts are seen on the scalp above the size of a walnut or billiard-ball, nor are solid tumours often met with of great magnitude. I have seen one of the latter kind larger than the fist removed from over the occiput. Occasionally sarcomatous tumours are so fixed to the cranium, that the propriety of attempting their separation may well be called in question. If, however, there is reason to suppose that the growth is only on the surface, or, at all events, is not connected with the inner table or lining membrane, their removal may, under favourable circumstances, be resorted to. There is a cast in the Museum of the Royal College of Surgeons of an enormous growth on the right side of the head, which was successfully removed by Sir Everard Home. The tumour extended from above the level of the right parietal bone as low as the shoulder of the same side, and greatly exceeded the size of the head. It consisted of "fat mixed with a steatomatous substance" towards the apex, "and wholly of bone," where it was connected with the right side of the os frontis, and although two operations were required (one performed on the day succeeding to the other), the recovery was complete. The operation was done in October, 1816, and the patient for a long time after acted as a nurse in St. George's Hospital. A drawing of the case is to be seen in Sir Everard's tract "On the Formation of Tumours."

Sarcomatous growths, when of considerable size, are usually in close contact with the pericranium, and this membrane often comes away with the mass. In instances under my notice granulations sprang up from the bone; but it is not difficult to conceive that necrosis might follow; or, should suppuration ensue, it is possible that matter might collect between the cranium and dura mater. Incisions may sometimes be necessary to facilitate the removal of necrosed portions of bone here, and may also be required in the treatment of aneurisms by anastomosis, but no special rules further than those already given in different parts of the volume are applicable to this locality. In incisions required for the latter disease, the surgeon will of course be prepared for copious hemorrhage; but I may here caution the young practitioner that the bleeding is usually very active from all incised wounds of the scalp, whether this structure be in a state of health or not.

The practice of puncturing through the anterior fontanelle with a
small trocar and canula, such as are exhibited in figure 288, in cases of chronic hydrocephalus, is occasionally worthy of trial. It is a proceeding which can be thought of only in early infancy, while the over-distended cranium is as yet soft and pliable, and is certainly one attended with considerable immediate danger,—not from the puncture, which is a very simple matter, nor from the sudden escape of fluid, nor from wounding either a vessel or the brain, but from the inflammation likely to succeed. I have seen several instances where the method was resorted to, and the first which came under my notice occurred in the practice of the late Dr. William Campbell, of Edinburgh. The patient was a new-born infant with congenital disease: a puncture was made a little to one side of the mesial line (to avoid the longitudinal sinus), a large quantity of fluid was evacuated, and a roller compressed the head to a natural size. No bad effects followed, but in the course of a few weeks the fluid had again collected: another puncture was made, and death from inflammation ensued.

Within these few years three other cases have come under my notice: one was treated by my friend Mr. Storks, the other two by myself. In Mr. S.'s case the operation, which required to be repeated, produced no ultimate benefit, for the patient died. In one of my own cases, sent to me by my friend Dr. Imlach, of Liverpool, in which the puncture was made with the sanction of Dr. Robert Ferguson, there was no improvement after half-a-dozen different operations, while upwards of sixty ounces of fluid was evacuated; and though the child survived these proceedings for several years, I doubt if the practice was of the smallest permanent service. The head was as large as ever within a few weeks after the last operation, and continued gradually to increase ever after. This child subsequently died without any mitigation of the principal features of the malady. In the other instance I operated with the concurrence of Dr. Robert Lee; but the case was a most unfavourable one for the practice, for, though the infant was very young, the ossification of the cranium was such, that the head could not be brought near to a natural size, even when a considerable quantity of fluid was withdrawn. The fluid speedily accumulated again, and death occurred some weeks afterwards. Through the kindness of Mr. Angus, of Frith Street (who had consulted Dr. Lee and myself on the case), I had an opportunity of examining the head after death, and found, as I had anticipated, that the convolutions over the ventricles were so expanded,
that the medullary substance was scarcely thicker than a common wafer. So far, then, as my own experience enables me to give an opinion, I should not be sanguine of great success from such a proceeding, although the example of Dr. Conquest, and others of repute, who have frequently performed the operation, is sufficient sanction for a continuance of the practice in all favourable-looking cases.

CHAPTER III.

OPERATIONS ON THE EYELIDS, ORBIT, AND EYEBALL.

Incisions may be required in the eyelids, and certain operations upon them are sometimes necessary. Inflammation in the eyelids usually causes great tumefaction, and occasionally in such instances lancet punctures, as in the case of erysipelas, are required; but these need no particular comment here. Sometimes freer incisions are necessary to permit the escape of matter, as abscess not unfrequently follows the latter affection. In such cases the lancet or knife should be carried in a horizontal direction, as the cicatrix will thus be less observable in the natural wrinkles of the skin.

Various little operations are required in these parts. For instance, a surgeon may be asked to extract one or more of the eyelashes in the case of trichiasis, and for this purpose each offending hair must be seized with well-pointed forceps (p. 5) and extracted by the root. Should others grow, or should the margin of the eyelid prove a source of irritation to the surface of the ball, and in the event of the latter condition (resulting probably from chronic inflammation, ulceration, and suppuration of the parts, or from diseased secretion of the Meibomian follicles) resisting the ordinary soothing, or stimulating treatment generally resorted to in such cases, then it may be deemed advisable to remove a small slip of the diseased part with the knife or scissors. Perhaps the latter instrument will be found most convenient in this situation, where the textures, from their mobility and slenderness, offer little resistance to the edge of the knife. It occasionally happens when some of these affections of the ciliary margins heal spontaneously, that the aperture of the eyelids is so much diminished in size that the knife is required to open up the unnatural adhesions, but no particular directions for such a proceeding seem necessary.

In some instances the margins of the eyelids and the cilia are completely inverted (entropium), and thus excit inflammation of the surface of the eyeball. The upper lid is perhaps most commonly affected in this way. The condition occasionally results from changes induced in the eyelids by acute and severe ophthalmia, and is remedied by those means which are of service in the latter affection; but sometimes it is present independent of this disease (excepting in so far as
it itself excites the mucous surface), and then it seems to depend either upon a contracted state of the margin of the lid, or of the edge of the orbicular muscle, or relaxed condition of the skin. Whether the latter is the cause or not, the entropium is easily remedied, as a last resource, by tightening the skin in this way:—A horizontal slip of it should be cut away with scissors; then the edges should be brought into contact by means of stitches, and thus the eyelashes are turned out and retained in their proper position. The slip of skin should be about an inch in length, and two or three lines in breadth: it may be seized, raised, and held steady with common dissecting-forceps, or such as are made for the express purpose, with broad flat points, which include the portion of skin about to be removed. Scissors, such as those referred to in pp. 4 and 35, will answer for these proceedings, although most generally those having a slight concavity at the cutting part of the blades are selected. I have seen a portion of skin, of the extent above mentioned, destroyed by strong acids; but, from what has been stated in the introductory part of this volume on the use of caustics in lieu of incisions, it may be perceived that I should not recommend such means here. Various ingenious plans of treating this condition have been devised by Ware, Crampton, and others, but that above described I have often seen to answer admirably.

In other instances the eyelids are everted, and the condition is termed ectropium. Sometimes it arises from tumefaction of the conjunctiva in acute ophthalmia (especially in a purulent form), on other occasions it seems to result from relaxation of the margin, and also of the mucous lining, whilst again it is often caused by contractions of granulations in the vicinity. It is most frequently seen in the lower eyelid, although inversion and eversion may be noticed on either.

In purulent ophthalmia the proper treatment of the disease serves to cure the eversion. Doubtless, the swelling in such cases is chiefly connected with the eyelids, but it may be also occasioned by the tumefaction of the conjunctiva on the surface of the globe, and it is in such cases that the mode of relieving tension, so strongly recommended by Mr. Tyrrell, may be most advantageously resorted to. The incision with lancet, knife, or scissors, should be made in a direction parallel with the course of the superficial blood-vessels; and thus, whilst relief is given by permitting the escape of serum, destroying some of the enlarged vessels, and lessening the distension of others, sufficient will be left to preserve the vitality of the cornea; and thus also, as that gentleman supposed, diminishing the chances of sloughing of this part, which is by no means unusual in this acute form of inflammation. If the incisions are made in the conjunctiva of the eyelid, they may be carried in any direction which shall be found most convenient.

When the eversion depends on chronic relaxation, such astringents as may bring the mucous surface into a more natural condition may be of service; but often it will be advantageous to remove a slip of the membrane by scissors: a portion of about a line in breadth and three in length may suffice. At first, of course, there will be no
ECTROPIUM. TUMOURS ON THE EYELIDS. 471

benefit, but as the granulations on the wound contract, the margin of the lid will be gradually drawn into a proper position against the ball. When this does not suffice, a piece of the margin of the eyelid should be cut out in this V form, and its edges drawn together by a single stitch, which will bring it against the orb at once, and if union occurs (as it almost invariably does) the affection is thus more speedily cured than in any other way. The part removed includes a portion of the cartilage. The operation may be done either with a sharp-pointed bistoury or with scissors such as those displayed at p. 35, and I need scarcely add, that the needles and threads for the sutures in these proceedings on the eyelids should be finer than might be used in most other parts of the body.

If the ectropium results from scars on the neighbouring parts, it will seldom happen that much benefit will be conferred by surgical interference. It is, however, in such instances that the surgeon is most anxious to exhibit the resources of his art, as the condition, besides its unseemly appearance, is productive of great annoyance and much injury to the eyeball; for, in consequence of the constant exposure, the conjunctiva becomes affected with chronic inflammation, and the cornea itself at last loses its transparency. Attempts have been made to put matters right by dividing the cicatrices, wherever they seemed to prevent the eyelid assuming its proper place. After severe burns, or for the depressed scars resulting from chronic strumous abscesses, and probable loss of bone, such trials have been made, but usually with little or no benefit; for, as the wounds have healed, the granulations have by their contractions brought the parts again into their previous mal-condition. In such instances a portion of skin might be raised from some neighbouring healthy part, twisted round, and laid in the gap of the wound at the cicatrix, so as to make up the deficiency occasioned by the original loss of substance. Such a plan has occasionally, in the hands of Græfe, Fricke, Dieffenbach, Serre, Mütter, Pancoast, and others, proved of benefit. I have often seen operations done in examples of this kind, and have myself occasionally performed them; but although I must admit that benefit has sometimes resulted, in many instances I should not be very sanguine of happy results.

Tumours are a more common cause for the use of the knife here: encysted steatomas are often met with, but frequently the contents of the cyst are thinner: sometimes a fluid of the consistence of cream is found within them, and now and then small hairs, similar to eyelashes, project from their inner surface; in one instance the growth seems more in contact with the skin or mucous membrane than in another, and occasionally the bulk is such that it comes equally close to both surfaces.

When a cyst is small and close upon the mucous lining, as is most generally the case, a cure may sometimes be effected by opening it
with a lancet carried through that texture. For this purpose the eyelid must be everted in this way: A probe should be laid horizontally upon it above or below, according to the lid affected (the upper is the usual seat of such tumours); then the eyelashes should be seized by the forefinger and thumb, and by pulling them and pressing in a proper direction against the margin the mucous surface will be everted, when a lancet can be thrust into the cyst and its contents squeezed out. The lid may then be restored to its natural position. Possibly a collection may again form, and it may then be treated in a similar manner; but, in addition, the interior of the cyst should be touched with a pencil of lunar caustic; or a portion may be cut out with scissors. Sometimes such growths may be dissected out with a scalpel, whilst the lid is thus everted, and although any of these proceedings may be comparatively easy in some individuals, they will cause much trouble to the surgeon in others: indeed, there are few patients who can keep the parts so still as the operator might wish, and there are some in whom the orbicular muscle becomes so affected with spasm as to make it almost impossible to conduct such operations in a satisfactory manner. But in the present day the use of chloroform obviates most of these objections.

The supposed advantage of the above practice is to leave the skin without a scar; but in some instances I have seen much annoyance from accumulation of blood in the wound and cellular tissue around; and both on this account, and from the size of the tumour, as also its proximity to the skin, I deem it requisite in many such cases to remove the disease through an external incision. Here the wound should be made parallel with the wrinkles, as already stated, with reference to incisions for other purposes. Sometimes it will be easy to complete the operation without touching the mucous lining; in others, the whole thickness of the lid will be divided; and I have myself been startled at the first glance of the cornea appearing through the wound at a time when I did not imagine that the knife had passed so deep. So far as my own experience goes, I have not seen that more trouble results from such a complete division, although it may be best to keep the lining entire, if this can be done. One or two stitches so applied that the thread shall not come in contact with the eyeball, will keep the edges in accurate apposition. It is scarcely necessary to add, that in all such operations the succeeding inflammation should be carefully watched; it rarely happens that it extends to the globe, yet I have seen it so, and great mischief result therefrom.

These proceedings are ranked among what are usually characterized as the minor operations of surgery; they are simple enough, certainly, yet the young surgeon will find that they require much nicety of manipulation, and try his patience to a greater extent than those of a more formidable and palpable kind. Where the parts are so moveable, a sharp knife is highly desirable, and the hook forceps (p. 31) will here be of great service in keeping the tumour steady.

Tumours occasionally form within the orbit, which require removal.
In many instances the diagnosis of such cases is difficult; both as to whether the growth is malignant or not, and as to its connexion. If the former, there is no time to lose, and removal should be proposed before all the parts around are implicated. Melanotic growths and those of a medullary character, supposing they can be discriminated, are such as these remarks apply to, as it must be highly desirable to operate before the eyeball is affected, or any of its important appendages. Then, on the other hand, it may be difficult to determine in how far the latter parts are involved, or possibly whether, in consequence of the surrounding attachments to the orbit, it would be proper to interfere with the disease at all. As tumours in this situation increase in size, they generally cause protrusion of the eyeball; ultimately, by the stretching of the optic nerve, and possibly by altering the shape of the organ, causing loss of vision; and this may occur whether the growth is connected with the globe or not. In non-malignant disease, unless the swelling is evidently increasing in size, and causing the changes last alluded to, a prudent surgeon would not think of urging an operation, which at all times must be deemed very dangerous in such a locality, from the vicinity of the eyeball, as well as of the dura mater and brain; but in a malignant affection, as the patient's ultimate safety is sacrificed by delay, there should be no hesitation about the necessity for an operation; and should there be evidence to show that the eyeball itself is involved in the disease, the course of procedure clearly is to remove the globe with the malignant mass. Aneurism by anastomosis has now been frequently seen in this situation, and I need scarcely point out the necessity for an accurate diagnosis in such cases, as no attempt at excision would be justifiable.

Since Mr. Travers's successful treatment of this form of disease in this locality by ligature of the common carotid, the operation has been repeated, and with excellent success.

Occasionally encysted tumours have been seen in the orbit, and some have been treated by puncture, others by excision. Solid growths have been more frequently met with, however, and though they may be in any side of the orbit, they are most common in the upper part. Sometimes the lachrymal gland has been the seat of adventitious growth; Davel, Todd, Lawrence, and others, have operated in such cases; and Tyrrell relates an instance where a surgeon, in removing a tumour from within the external angular process, under the supposition that it was an affection of this gland, afterwards found the organ in a healthy condition, attached to one side of the mass. In operating in this situation, therefore, it may be well to proceed cautiously, so as if possible to preserve this organ and its ducts. Incisions in the course of the supra-orbital ridge will usually answer best in the upper part of the socket, but vertical ones have been preferred on some occasions. Below, horizontal incisions also will probably be most suitable.

When the eyeball itself has to be excised, the operation may be done thus: The patient should be laid on the table with the face uppermost, and then, with a scalpel or bistoury, an incision should be made from
the external commissure, half an inch beyond the margin of the orbit, when the eyelids may be more completely opened by an assistant, especially if the skin be detached from the bone above and below this wound; next, the organ should be seized with an instrument, such as that here represented (fig. 289), and then the point of the knife should be carried between the eyelids and ball, so as to divide the conjunctiva; when, by carrying it deeper, and moving the organ from side to side with the instrument held in the left hand, the removal may be completed by dividing the muscles, optic nerve, and other textures. It will seldom happen that there is either difficulty or trouble in this proceeding; and the hemorrhage will probably be easily commanded by stuffing the orbit after the operation with charpie or lint. Afterwards caution must be taken to avert or subdue any high degree of inflammation, which, as may readily be perceived, must be more hazardous here than in many other regions.

Whether the tumour be large or small, the same style of operation will answer; if it is of considerable magnitude, there will be no necessity for the instrument to keep it steady, as the fingers alone may suffice for this; but whenever the growth is entirely confined within the eyelids, the instrument represented in the sketch will, in my opinion, be found superior to any other; if, however, one be not at hand, a single or double hook (p. 6) will answer the purpose, or a thread may be carried with a common surgical needle (p. 34) through the ball, by which the operator can move the part at will. In rare instances it may be requisite to remove portions of the eyelids at the same time; but in general a surgeon would be loth to interfere in this way with a case where the disease had extended so far.

Within these twenty years a practice has become common among oculists to remove the eyeball when it has become disorganized from inflammatory action, either of spontaneous origin or resulting from injury. In the favourite pastime of cover shooting the sportsman may have an organ damaged by a single pellet or more. Occasionally a drop of shot may lodge within the organ, but even a grazed wound of the kind is liable to be followed by inflammation sufficient to destroy sight, and in some instances a chronic painful inflammatory action is the result. This often baffles all ordinary modes of treatment, and excision of the damaged orb is under such circumstances not only justifiable, but a certain cure. For such an operation all is left in the orbit but the eye itself. There is no need to cut the skin at the outer ends of the eyelids, and from the comparative smallness of the wound it heals with great rapidity, so that in a week or
two an artificial eye can be worn, when the defect will scarcely be observable. An old-fashioned notion that when one eye is diseased the other is certain to be similarly affected, has been extensively acted upon in modern times, and even an inflamed eyeball has been removed under the pretence that the other was sure to go in a similar way. I believe the practice to be totally unworthy of the best doctrines in surgery, and I know of many instances in corroboration of this statement.

On the projecting angle near the inner extremity of each eyelid, the puncta may be observed, and a bristle with a smooth end may be pushed into each, when, by conducting it in a horizontal direction, it will pass along the lachrymal canal into the sac, and possibly into the nasal duct; the point of a slender pin may be used in the same manner, or a small silver probe such as that recommended by Anel. These proceedings are occasionally resorted to in consequence of obstructions to the natural course of the tears either from thickened mucus or from stricture, but, in so far as my experience goes, are of very little service. Mr. Bowman has proposed in some of these cases to slit open a punctum and part of duct, and much good in permitting the free passage of tears has, I understand, been the result.

The nasal canal can be examined from below upwards, by means of a common-sized silver probe. To effect this, the instrument should be bent at a right angle, about three-fourths of an inch from its point; then this part should be carried along the lower floor of the nostril, until it arrives below the anterior extremity of the inferior turbinated bone; next it should be turned upwards, when, with a gentle movement, it will slip into the lower orifice of the passage, and may then be pushed higher, until it causes the skin to project a little below the inner canthus. The probe may now be removed; and if the eyelid, and particularly the orbicular muscle, be drawn towards the malar bone, a round cord-like projection will become apparent, below which, if a puncture be made with a lancet, scalpel, or bistoury, in a direction downwards and slightly towards the nose, the lachrymal sac will be opened, when a straight probe can be pushed from the orifice down into the nostril.

These manoeuvres may be required when, from obstructions in the nasal duct, the condition termed stillicidium lachrymarum is present. If there be a fistulous opening in the sac, whether from previous puncture or from ulceration, a straight probe may be pushed downwards through it; and in such a case slender instruments may be used at first, when, as dilatation goes forward, they may be gradually increased in size. Catgut probes (bougies) have sometimes been used on these occasions—or steel ones have been preferred—and in other examples attempts have been made to overcome the obstructions by injections of water conveyed through a small syringe, recommended for the purpose by Anel, whilst in rare instances a column of mercury has been used with a similar object. From my own limited experience with these slender instruments of Anel's, I cannot express great confidence in their use; and Mr. Tyrrell seemed to think them of but little service.
The late Mr. Morgan recommended a curved steel probe of this shape (fig. 290) for the examination of the nasal duct, when it is made from below.

Supposing there is no opening in the sac at the inner canthus, and that an operation is deemed necessary to restore the proper course of the tears, it may be performed in the following manner: The patient being seated, the surgeon, standing behind or in front as he may choose, should put the tendinous cord already alluded to on the stretch, and then push a sharp pointed bistourey into the sac immediately below; this being done, he should next elevate the blade a little, to make room for a probe or style, which he should thrust through the opening in the skin into the sac, and from thence along the nasal duct into the lower part of the nostril. The position of the knife is exhibited in the accompanying figure (291); it will be observed that it is almost in a straight direction downwards, the upper part of the blade resting, as it were, over the notch in the supra-orbital ridge. The orifice in the skin may be of the same extent as the breadth of the blade, or the latter may be so managed, if it is desired, as to make it somewhat more. I have occasionally found in this proceeding some difficulty in passing the probe into the lachrymal sac; especially when the knife has been withdrawn altogether; therefore, I recommend, that the point of the instrument should, although elevated a little, still be left in the sac until the probe is introduced, along its flat surface. After the point of the latter has been introduced, it may even then be troublesome to carry it into the nostril; sometimes it will pass down the sac, at other times along its side; occasionally I believe it perforates the bone; in other instances it is purposely passed directly into the nostril through the osseous texture wherever that can be conveniently done, and with the latter object the os unguis may be found the most eligible. Although in general it will be desirable to pass the probe through the nasal canal, it is perfectly proper, on some occasions, I conceive, to make an opening into any part of the nostril which seems most appropriate. The probe that may be used on the occasion is a common silver one; but it would be well at once to use what is termed a style, which is a short probe, such as is here represented (fig. 292), of a length sufficient to reach from the orifice in the skin to the inferior nasal fossa, and having at its upper end a button-
like head, to prevent its slipping altogether within the passage. This instrument may be slender at first, and thicker ones can be introduced afterwards, so as to dilate the opening gradually. A full-sized one may, however, be used at once, and retained or withdrawn according to circumstances. It is customary to keep this style in the duct for several weeks, during which the tears will flow partly by its side into the nostril, and partly, perhaps, over the eyelid, or from the orifice in the skin; then perhaps it may be withdrawn, when the tears will flow entirely into the nostril; it may, however, be found necessary to continue its use for a longer period, and occasionally it must be kept in ever afterwards. If removed, the orifice in the skin usually closes within a few days or weeks, although it continues open in some instances; and when there is a copious supply of tears, a drop or two will now and then escape; if worn constantly, it is customary to blacken the button-like head, or to have it coloured like the neighbouring skin. The style is usually made of pewter, which answers as well as silver or any other more costly metal. Sometimes instead of this solid probe a tube is introduced, of such length that it passes fairly within the duct under the skin, where it is intended to remain permanently. Mr. Tyrrell found such a plan succeed very well.

Instead of a probe or style, I have in some instances first introduced the point of a director along the side of the blade, and then conducted a style down upon its groove. The late Dr. Lubbock, of Norwich, proposed using a steel needle made for the purpose, something like a director, but having a sharp point,—like that of the exploring needle referred to at p. 12, and represented on p. 79, and that this should be thrust into the sac at first, instead of a bistoury, when the style can be immediately and with ease carried downwards along the groove. In using any of these instruments, the surest proof that the nostril has been reached is, that the blood flows in this direction; but sometimes, to make certain that the point is fairly through below, a probe is passed into the nostril, and made to touch the one introduced into the sac.

Sometimes the surgeon's interference is required for the purpose of removing foreign substances which get between the lids and ball, or actually penetrate the surface of the latter, such as particles of dust, insects, grains of powder, scales of iron from the blacksmith's anvil, &c.; but other rules than those which a knowledge of the anatomy of the organ, the use of instruments on such delicate textures, and ordinary mechanical principles will indicate, do not seem to require notice here. Sternotatories, and all means likely to excite a copious secretion of tears, may be of much service, by causing the latter to wash the mucous surfaces. Raising the eyelids, using a syringe and tepid water, a camel-hair pencil, or forceps, will usually insure success.

In opacity of the lens, whether congenital or in the more common form occurring in advanced years, the cataract, as it is termed, can be removed from the axis of vision, and the proceeding may be effected in various ways. That by couching, once perhaps, the most com-
mon, may be accomplished on the living body in the following manner:—The patient should be seated on a chair with a back sufficiently high to permit his head to rest against it, and an assistant should be instructed to keep it steady. Then the surgeon should sit or stand in front, according to the height of the seat on which the patient rests: next, he should place the fore and middle finger of his right or left hand, as the case may be, upon the margin of the lower eyelid, and whilst pulling it slightly downwards should apply gentle pressure upon the globe with their points, while at the same time the assistant who holds the head should elevate the upper lid, and steady the eyeball with the points of his fingers: thus these being opposite to those below will serve to keep the cornea uncovered and the ball itself steady: then the operator should pass the point of such a needle as that delineated in figure into the interior of the eye, by piercing the sclerotic about a line's breadth from the cornea on the outer side of the globe, and nearly on a level with the commissures: a slight plunge is required to pass the instrument through the tough tunic, but as soon as it has entered it passes readily along behind the iris, and when the point is visible through the pupil (which should have been dilated by the previous application of belladonna), it can then be placed against the opaque object, which may now be treated according to circumstances: if the lens be soft, the instrument must be carried across it in various directions, and several portions should, if possible, be detached and pushed forwards into the aqueous humour in the posterior or even anterior chamber: if the cataract be hard, then the needle should be pushed against it in such a way as to force it downwards and backwards into the vitreous humour: if it is thrust almost straight downwards, without any other change of position, the proceeding is usually termed depression, if laid backwards, so that its anterior surface is placed uppermost—reclination is the term to denote this manœuvre, and in either instance it will be observed, that the object is to make a clear passage for the rays of light towards the retina: this being done, the instrument should be withdrawn, the eyelids closed, the patient kept quiet in a dark room, and every care taken to avert injurious inflammation, for a severe action of this kind is what is chiefly to be dreaded after the operation. In two or three weeks, provided everything has gone on favourably, the light may be gradually admitted, and in the course of time the sight may become so perfect that the smallest print may be distinguished.

Here is an occasion where ambi-dexterity (p. 4) may be useful, although it is not absolutely requisite. If the operator is in front of the patient, he may use his right hand on the left eye, and his left on the patient’s right globe: if, however, he has not confidence in using the left, he can in operation on the right eye stand behind the patient and then use the right hand, with which the necessary movements are most generally made. In every instance the little finger should rest against the malar bone, and thus the double object will be obtained of given great steadiness to the hand, and permitting it to follow any slight movements of the patient’s head, although every
care should be taken to keep the latter as steady as possible. It is for
this purpose that I recommend the high-backed chair, as being pre-
ferable to the breast of an assistant, although the latter is very fre-
quently selected. Sometimes the patient is laid on a table face upper-
most, and thus whilst greater steadiness is, perhaps, secured, the
operator can use his right or left hand at will.

The needle which I preferred for such a proceeding, when I occa-
sionally performed such operations in early years, was that commonly
called Scarpa's, here (fig. 293)
represented of the ordinary size;
it is spear-pointed and slightly
curved, and, in my opinion,
answered as well as any other.

Perhaps it may be more trouble-
some to disentangle from the cataract after it has been couched, than the
flat-shaped point of Saunders's instrument, although here I cannot speak
from my own experience, not having used the latter on the living subject.
With Scarpa's, however, I have noticed both with myself and others,
that the cataract was occasionally raised slightly in withdrawing the
point; but even in instances where the needle has separated readily
I have often seen the lens rise again and require an additional push
downwards. On this account it is well not to remove the needle
entirely until it is seen that the opaque object continues in its new
position.

The lens may be removed from the axis of vision by pushing the
above instrument, or any other of convenient sort, through the
cornea and pupil, but there is an objection to this on account of the
scar that might be left in the transparent cornea, and the greater risk
of injuring the iris: the bad effects of the former might be avoided
by keeping the instrument near the circumference of this part, but
the iris would always be more or less in the way, and, moreover, no
particular advantage seems to attend the proceeding to induce a pre-
ference over the other.

In general it is troublesome to get the eye so perfectly still as to
enable the operator to pass
the point of the needle into
the exact spot he may wish,
but when once it has perfor-
ated the sclerotic the globe
is, as it were, fixed on the
needle, and can then be kept
perfectly steady, however
restless it may have been
before.

Drawing 294 will serve
to illustrate the above de-
scription. The needle some
may think too far from the edge of the cornea, but others would
introduce it even farther off.
In recent times it is generally preferred to extract the cataract through an opening in the cornea, and the operation may be done thus:—The patient being laid on his back, and the head, eyelids, and eyeball fixed in the manner already described, the surgeon with his right or left hand, as he may choose, passes Beer's knife,—represented in figures 295 and 296, across the anterior chamber from one margin of the cornea to the other, with its back about midway between the upper and under edge of that part, whereby he divides about one-half of the circumference of the tunic, and makes an opening sufficiently large to permit the escape of the lens. To facilitate the latter object it is generally requisite to introduce a couching needle, or other such slender instrument, through the wound, to touch the capsule of the lens in such a manner as to make an opening sufficiently large to allow the cataract to slip outwards with a slight pressure on the globe, until it passes through the external incision. Possibly a little scoop, or curette as it is called, passed behind the lens, may be requisite to expedite the escape. When this has been accomplished, and it is seen that the iris has not slipped through the wound in the cornea, the edges of the latter should be carefully placed in apposition, the eyelids closed, and the treatment afterwards conducted as in the instance of couching, being modified of course by circumstances.

It is evident that the knife in an operation of this kind can only be passed from the temporal margin of the cornea. It has been proposed to touch the front of the capsule with the point of the blade as it is carried across, but there is a risk in so doing of the aqueous humour escaping, and at the same time carrying the iris against the sharp edge of the knife: it is therefore, perhaps, better not to attempt this, for in all cases, even when it is not done, the difficulty will be great enough to avoid wounding this important structure. To lessen the danger it is necessary before operating to see that the iris has been opened to its fullest extent by the influence of belladonna. The section of the cornea may be made either on the
upper or lower margin, some having preferred the latter as being most convenient, others the former, as the aqueous humour does not escape so readily, either at the time of the operation or afterwards, and figures 295 and 296 will further illustrate the general description.

I need scarcely say that all the aqueous humour escapes with the lens, or probably before it is started from the capsule, and, moreover, that if the pressure be not cautiously applied, part of the vitreous humour also may be squeezed out, possibly even the whole of it, as has happened,—when of course the organ is completely destroyed. Some (Mr. Guthrie for example) seem to put little importance on the escape of part of the vitreous humour,—indeed the gentleman whose name I have mentioned had a fancy that the loss of a portion of it was rather an advantage. Most authorities, however, appear anxious to inflict as little injury on the organ as the necessity demands. Immediately after the operation the cornea appears somewhat wrinkled and of a milky colour, but if all goes on favourably a full amount of aqueous humour is soon secreted again, and the cornea resumes its tenseness and transparency.

In operations for extracting cataract the use of chloroform is usually forbidden, as during the unconscious state of the patient some action with the eyeball, head, hands, or eyelids, might frustrate the best intentions of the operator. The operation has, however, been frequently performed with success under anaesthesia.

There are various other operations connected with the eyeball which my limits will not permit me to dwell upon. The removal of foreign substances from the surface, the mode of using the lancet in dividing enlarged vessels—as in chronic inflammation, the manner of dissecting off a pterygium, of separating an encanthis, of removing a staphycoma, of making an artificial pupil, by tearing or cutting open the iris, or by removing a portion of the structure, as in the modern operation of iridectomy, and conducting various proceedings on the iris, are all described at length in works devoted specially to ophtalamic surgery, but which, in such as this, may on that account be omitted.

The operation for strabismus, however, I must not pass over without description. The merit belongs to Dieffenbach of having discovered, that division of one or more of the muscles of the eyeball permits the others to restore its natural position; thus, in strabismus convergens where the inner margin of the cornea approaches or is concealed by the plica semilunaris, division of the internal rectus allows the other muscles to give the globe a more natural balance; and so in that form termed divergens, the section of the external rectus permits all to go right. Since the principle has been established an infinite variety of modifications have been proposed and executed, and considering the zeal with which the subject has been cultivated, the success of the operation, its advantages and simplicity—both as regards its performance and results, it seems strange that such a condition as a confirmed squint should now—a-days ever be seen.

The operation may be done thus: Supposing that the right eye is
affected with convergent squint, the patient seated on a chair, or laid on a couch, with the eyelids held open with the fingers, or the upper lid with a Pellier's elevator, such as that exhibited in figure 297, or by a spring instrument like that in figure 301, and then a small double hook—made expressly for the purpose—and such as that seen on the eyeball in the next drawing (298), should be passed into the sclerotic, or through the conjunctiva at all events, about a line's breadth from the inner margin of the cornea. Both of these instruments should be held by an assistant, and the eye being drawn slightly outwards, and at the same time fixed by the hook, the surgeon should seize, with well-pointed forceps (p. 5,) a fold of mucous membrane at the inner canthus, and with scissors such as one of those represented at p. 35, should divide the conjunctiva in a vertical direction as is represented in drawing 298, so as to make a wound about half an inch in length between two and three lines from the cornea: the tendon of the internal rectus will thus be laid bare, and can then be divided with the same instrument; next, the hook should be removed, and the forceps loosened, when if it be found that the eye is straight, and can no longer be turned towards the nose, the operation may be deemed complete. If, however, the squint still continues, the eye must be again fixed and the scissors reapplied, when some remaining fibre, which probably keeps the organ in its wrong position, may be divided. It may even yet be necessary to cut again, and some of the fibres of the superior rectus have been divided on such occasions, with probably part, if not the whole, of the superior oblique. It has rarely happened that the squint has not been relieved in such instances, but in some, to secure symmetry, the external rectus of the other eye has been divided. Notwithstanding the proximity of the eyeball, as also extensive exposure of the sclerotic, it has seldom occurred that serious injury has been done at the time, or that bad results have followed. I have myself seen one instance only where injurious inflammation and sloughing ensued, and have heard of a case where the sclerotic was punctured, though doubtless more damage may have been done than has come to light.

The same instructions may answer for almost every form of strabismus; but many other modes of operating have been preferred:
thus the hook or the forceps, one or both, may be dispensed with, and instead of scissors a small curved knife like this (fig. 299) has been used to open the conjunctiva; then a curved director (fig. 300), has been carried behind the tendon, and the latter has been divided by running the blade along the groove; or sometimes the tendon has been elevated on a blunt hook and cut with a knife or scissors; but I shall not attempt to describe all the modifications that have been proposed, and may only state my conviction, that the operation may be accomplished in half a dozen different ways at least, and with as many different instruments; each and all being selected more, perhaps, to please the fancy of the operator, than from possessing any remarkable superiority. Chloroform suits perfectly for the above operation.

Instead of the hook represented in figure 298, the common dissecting forceps (fig. 6) may suffice to fix the ball, and at the same time pinch up the mucous membrane prior to the application of the knife or scissors; and instead of the elevator (figs. 297-8) an instrument of this sort (fig. 301) will serve to keep the eyelids open. The curved wire is so elastic at its principal bend that, when the two sides closed are put between the eyelid and allowed to open again, they so thoroughly uncover the surface of the ball that the surgeon can proceed without trouble from the eyelid closing.
The skin of the nose in some individuals increases so much in thickness as to become a prominent swelling (Lipoma) which, besides its unseemly aspect, causes great annoyance from its size and weight, for sometimes the top of the organ becomes so large that the possessor cannot see straight before him without turning the head to one side, and can neither eat nor drink without being obliged to hold the offending part out of the way. Such a condition may easily be remedied by paring off the redundant material, and leaving only the cartilages with some cellular texture upon them. The wound, if all goes well, in such a proceeding must heal by granulation; and, pro-

vided that neither too much nor too little has been taken away, a most respectable looking feature may still be left. Sometimes the morbid growth is entirely on the apex, at others on one ala, and it is seldom otherwise than of a most ruddy hue. No rules need be given about such proceedings: the thickened parts may be dissected off in one mass or piecemeal, at the convenience of the operator: the finger should be introduced into the nostril to keep the surface steady, and almost invariably a good deal of bleeding may be expected, which will, however, cease with the application of cold.
Mr. Hey has related the history of a case of this kind in his admirable work on Surgery, and such an operation as that which he performed has been frequently repeated by modern surgeons, among whom I may especially name Mr. Liston. Figures 302 and 303 give good illustrations before and after such an operation in my own practice. It was remarkable in this instance how speedily the extensive raw surface left by the operation was healed over with a healthy cicatrix.

Fig. 303.

A deficiency of this organ, from accident or disease, is of more common occurrence than a redundancy, and, unlike the latter,—which among certain novelists, poets, and poetasters, has been rather a theme of admiration,—its appearance is generally so annoying that the individual who has been unfortunate enough to be "curtail'd of this fair proportion," whether by disease, accident, or otherwise, is usually willing and anxious to submit to whatever may be thought likely to improve his facial aspect. It may be a question with both patient and surgeon in what manner this can be done,—whether it shall be by means of some artificial substitute of wax, wood, ivory, metal, pasteboard, gutta-percha, or other material, or that it shall be effected by a kind of transplantation of skin from a neighbouring part. If the latter is preferred, the surgeon is more immediately interested, as the work of restoration lies entirely with him. Supposing that the apex and alae have been completely destroyed, or have sunk in such a manner that they cannot again be raised, a substitute for them may be made in the following manner:—The patient being seated, the surgeon first takes a portion of soft leather, and cuts it with
scissors to the size which may be thought best, and of a shape such as the space within the dotted lines on the forehead in fig. 304: next he lays this upon the brow and carries a scalpel round it down to the periosteum; leaving a portion of the skin at the root of the nose untouched: this flap should be raised by dissecting close upon the periosteum, and then allowed to lie with the cut surface exposed to the air until other steps have been accomplished. Now the knife should be carried, in the course of the dotted line in the figure, down the sides of the old nose, and a deep groove should be made by keeping close to the bones, or even by paring out a portion of the skin: the cut surfaces should be carefully sponged with cold water, and should the blood continue to ooze, the whole must be exposed to the air for some time longer. When all bleeding has ceased, the flap must be turned down,—its root being twisted half round, so that the cuticle may still be kept outermost: the edges must then be accurately applied to the wounds on the face, and retained by two or more stitches on each side. At this time the flap will be flat and loose, but it should now be raised by stuffing in portions of lint, until it projects to the full extent. A stitch should then be introduced at the lower part of the gap in the forehead, the open surface above being left to heal by the second intention.

The above proceedings require a good deal of nicety on the part of the operator, and various circumstances must be carefully attended to. First, the flap should be so large that, at the period of the operation, and for some weeks or months after, it should seem to be more full than there is occasion for: in the course of time it will contract so much that at last, when the newly-made organ has acquired its permanent shape, its size will not be greater than may be required. It should be remembered that, as soon as the knife is carried through the line on the brow, the skin which it has circumscribed will contract a little, and therefore due allowance should be made for this when the leather is being shaped; moreover, as the cheeks separate when the wounds are made on the face, the knife should not be placed too far from the mesial line, for fear of making the base of the new nose too broad. Then, care must be taken that the root of the flap is not left too narrow for fear of deficient circulation, and it should neither be twisted hard, nor compressed by the stitch between the eyebrows.
In order to bring the flap down to a proper position, and to obviate stretching and pressure, the root will sometimes require to be slightly elongated by carrying the incision a little lower on each side.

The bleeding from the wound on the forehead will be copious; but ligatures are seldom required. The gap is very considerable at first; but in the course of time, especially if care has been taken in the dressings, the cicatrix will not be very conspicuous. The stitches on the cheeks must be removed on the third or fourth day, when, in all probability, complete union will have occurred: the free edges of the flap will heal by granulation, and until cicatrization has become complete the part must be carefully supported with lint, which may be introduced in such a way as shall conduce greatly to the ultimate shape of the organ.

After the lapse of three weeks or a month, when all the sores have healed, the root of the flap should be cut across. It will be observed that as yet the skin immediately under this part has not been touched: now, however, an incision should be made, so as to admit the upper extremity of the flap, which for this purpose must be cut in the shape of a wedge: this wound having also healed, and when the vitality of the transplanted skin seems vigorous, a new columna must be formed in this way:—The patient laid on a couch, or being seated and his head held back, the surgeon should pass the point of a narrow bistoury into the root of the upper lip, a little to one side of the mesial line, and cut downwards until the instrument passes the free margin: again he should introduce it at a corresponding part on the other side, and, by carrying it downwards in the same manner, a portion of the lip, about three lines in breadth, will thus be detached, excepting at its upper end: here the frenum must be divided, and the tissues so far separated from the bone as to permit the slip to be put into the natural position of the columna. Next two or three hare-lip pins must be used to bring the surfaces of the lip together, so as to exclude this mesial portion: then the extreme point of this (the red margin) should be cut off; and a suitable surface prepared for it with the knife, on the inside of the apex of the flap, where a small prominence has purposely been left, as indicated by the line on figure 304: the two points should now be approximated and kept together by a twisted suture;—and so the columna is formed. The wounds must be treated in the ordinary way, a small portion of lint being retained in the aperture of each nostril.

Various modifications of these proceedings must be left to the discretion of the surgeon. In an instance under my care in King’s College Hospital, after cutting through the piece of skin forming the neck of the flap, now the new nose, I so fashioned my incision, that I cut the apex of the new nose into a wedge, which I fitted on at the bridge of the nose, and the other part I turned up again to its original situation between the eyebrows, where, by a little application of the knife, I made room for it in its normal situation. These manœuvres on the whole proved very successful, particularly in keeping the inner ends of the eyebrows at their usual distance from each other. If a
small portion only of the original nose is deficient, the edges may be pared for the reception of the flap instead of a groove being formed in the cheek as above described. In some instances, when the original nose is sunk, the opening into the nostril is not sufficiently large; a portion should therefore be cut out at any convenient period, and perhaps, after a new columna has been made, will be most fitting when the apertures of the nostrils come under treatment—for here the knife may be required to scoop out or enlarge each. At all times, as much of the old nose should be preserved as possible, as it forms the best foundation for the superstructure.

The operation here described, in so far as regards the formation of the flap from the forehead, is similar to that done amongst the native Indians, and differs from that of the celebrated Italian professor, Taliacotius, who took the flap from the skin of the arm. The latter proceeding I need not describe, as it is rarely if ever performed in the present day. The formation of the columna is in the manner recommended by Dieffenbach, who, however, twisted the part so that the cuticular surface might still be outermost. But this seems to be a matter of little consequence: the mucous membrane soon becomes callous, and to lessen the risk of strangulation of the slip, I give a preference to the mode above detailed, which was recommended by Mr. Liston.

Figure 304 is a likeness of one of my own patients on whom a flap was formed in the manner described. The sunken state of the nose was occasioned by ulceration within, resulting apparently from scrofula. All morbid action had ceased ere I interfered; but some months afterwards, when there was promise of an excellent new organ, the disease appeared again, and to a certain extent marred the effect.

I have frequently performed operations as above described, and never seen any evil follow. To my astonishment, however, I found in a recent instance that the whole of the flap from the forehead sloughed without any perceptible reason.

In some instances the apex and alæ of the nose seem so entire, although sunken to a level with the cheeks, that the propriety of thus covering them may be doubted. Instead of doing so, Dieffenbach elevated the parts again, by slitting them into three longitudinal portions,—the outermost incisions being carried in the course of the lines on the cheeks in figure 304,—then he pared the edges of the slips so as to make each narrower within than without, like the stones of an arch; next he dissected the cheeks from the nasal margin of each superior maxilla, fitted the wounds closely by interrupted sutures, and then kept the whole prominently forward with a couple of long silver needles passed from one check to the other: but this latter proceeding will be best understood by a reference to the next figures.

A patient of mine (a young gentleman who had been vain of his personal appearance previously) was left after severe ulceration of the interior of the nose, in the condition represented in figure 305; the columna and the cartilaginous septum had been destroyed, and the vomer had separated by necrosis. Here I imagined that a modification of the proceeding of the Berlin professor might be advantageously
O P E R A T I O N S  O N  T H E  N O S E  A N D  N O S T R I L S.

resorted to, and accordingly proceeded thus: The patient being seated, the point of a small scalpel was introduced under the apex, and the alae were separated from the parts underneath; next the knife was carried on each side between the skin and the bones, as far as the infra-orbital foramen,—care being taken not to interfere with the nerves, when by passing the point of my finger below the nose, I caused the latter organ to be as prominent as could be wished. I now pushed a couple of long silver needles, which had been prepared for the purpose, with round heads and steel points, across from one cheek to the other, having previously applied on each side a small piece of sole-leather perforated with holes at a proper distance; then I cut off the steel points, and, with tweezers, so twisted the end of each needle as to cause the cheeks to come closer to each other, and thus render

Fig. 305.  Fig. 306.

the nose prominent. Figure 306 further elucidates the proceeding. Thus, by bringing the cheeks more into the mesial line, a new foundation, as it were, was given to the organ. Adhesion occurred in some parts, granulation in others; in the lapse of ten days the needles were withdrawn, and a few weeks after, when cicatrization was complete, the nose presented as favourable an appearance as could reasonably have been desired. Now a column was formed in the manner already described, and at last I had the satisfaction of producing such a result as that exhibited in figure 307. Here matters were still further improved by the addition of an artificial eye, to make amends (in some degree) for the loss of the original one, which had been destroyed by ophthalmia some years before.
It may happen that only a small part of the tip of the nose requires to be renewed, sometimes an ala, on other occasions a columna; in one case the nose may be awry, in another the bridge may be depressed, and for all these conditions the art of surgery may be made available. I need not dwell on these topics, however (indeed my limits will not permit me), and shall refer those who wish for more particular information to the works of Serre, Zeis, and the illustrious Dietrichbach (on the Restoration of the Nose), whose skill in rhinoplasties seems to have been such that he could repair or rear up this most important feature with all the genius of a Telford, and finish his handiwork with the Phidian touch of a Chantrey.

Occasionally in children foreign bodies, such as pickles of grain, peas, beads, cherry-stones, and such like objects, get into the nostrils, and require removal. I have known a cherry-stone or boot button remain for years, and the cases supposed to be disease of bone. A probe, a small scoop—such as the handle of a director (p. 12), a blunt hook, dissecting forceps, or instruments similar to that represented in cut 308, will seldom fail, if judiciously used, in effecting extraction of such substances; and as the patients are generally young, great advantage will be derived from the use of chloroform.

The mucous membrane of the nostrils is peculiarly liable to the development of tumours, which pass under the name of polypi. Usually the disease is in the shape of a gelatinous-looking mass of a pyriform shape, enveloped with mucous membrane, hanging almost loose in the nostril, being attached to the lining membrane by only a small neck. This attachment may be with any part of
such membrane; but I believe that it is rarely connected with septum. The tumour moves backwards or forwards during respiration, particularly in early stages, before it gets in a manner fixed by its enlarged size, and may usually be seen on looking into the nostrils. Sometimes a polypus is most in the back part of a nostril, and then its presence can only be judged of by obstruction to the passage of air, although when of considerable size it may be recognised by causing bulging of the soft palate, or possibly by projecting beyond the margin of the velum and into the pharynx. In certain cases, instead of narrow connexion with the nostril, the basis may be extensive, and this seems mostly the condition in examples when the disease has repeatedly returned after operations performed.

Fig. 309.

for extraction. Sometimes, instead of a polypus being gelatinous, its texture is of a fibrous character, and some such examples have appeared to me as if connected with or springing from the periosteum on the base of the cranium. When of this kind and connexion they are formidable tumours to meddle with.

When polypi in the nostrils assume such a size as to cause annoyance, whether from altering the tone of voice, preventing respiration through these passages, from protruding through the anterior openings, or so pressing upon the soft palate and into the pharynx as to cause difficulty both in respiration and deglutition, they should be removed by operation. In general, such an instrument as that represented in fig. 308, will enable the surgeon to effect his intentions, thus:—The patient being seated, the blades of the forceps must be passed into the nostril, one on each side of the growth, if possible, when they should be closed over its roots, as represented in fig. 309, and withdrawn by a twisting, pulling motion, so as to separate the disease from the mucous membrane above. In some instances this can be done readily, and with
one application of the instrument; in others it must be introduced again and again, when the substance is removed piecemeal; and the best criterion of the operation being complete is, that the patient can breathe freely through the passage. Sometimes it is necessary to repeat the proceeding in the course of a few weeks or months, as the ordinary simple gelatinous polypus, unless it be thoroughly removed, is almost sure to grow again.

In certain instances when the tumour is of considerable size a ligature may be most advisable: this being drawn tight round the root of the mass will cause its strangulation, when it will separate in the form of a slough. Whipcord, catgut, or silver wire, may be used on these occasions; perhaps the two latter are best from their elasticity, and either may be applied thus:—A portion twelve or eighteen inches long should be doubled, care being taken not to injure its elasticity at the bend; this part should then be pushed along the floor of the nostril until it reaches the pharynx, where it must be allowed to expand; and now the point of the forefinger or forceps of convenient length should be passed along the mouth into the throat, and so managed as to push the gut or wire behind and above the growth: when this is accomplished the ends must be introduced through a small double canula, such as that represented in fig. 310, which should be slid along upon them as high up as the root of the disease seems to extend, and thus the noose will be further up than the finger can push it; one end of the ligature may then be fastened to the ring at the side of the canula, and the other must be drawn so tight as to obstruct all circulation in the part; it may then, if allowed to remain, be fixed to the ring of the tube, and tightened from day to day, until the separation is effected. I have frequently used the ligature as thus directed; but have almost invariably drawn it out at once with the mass, which has, thereby, been removed at the time, and I have never seen reason to dread the hemorrhage which some seem to apprehend on these occasions. Sometimes I have found the part so compressible, that it came readily through the nostril in front; but occasionally I have withdrawn it by the mouth, and in such instances it is well to be careful in case of its dropping into the lower part of the pharynx, or possibly covering the orifice of the larynx. I once saw a patient swallow a mass of this kind larger than a walnut, which, however, did her no harm. If it could be effected with safety, I should on all occasions separate the part at once, instead of leaving it to slough; but if the latter were deemed most eligible, I should prefer a silver wire to any other ligature, and choose it, too, before the forceps, which have been recommended by Sir Charles Bell and others for the purpose.
When a polypus is very large in front so as to have caused absorption of the nasal process of the superior maxilla, the nostril may be slit open, and the disease extracted through the aperture by means of the foreeps. The external incision should pass from the junction of the nasal bone to the maxilla between the ala and cheek, as the subsequent incision will be less observed here than elsewhere. I have sometimes resorted to this practice, and have known a growth six ounces in weight successfully removed in this way. In some instances it may be deemed advisable and necessary to remove a portion of the superior maxillary, turbinate and nasal bones, to permit the complete separation of growths in the nasal fossa. Such operations have been performed by Syme, Faubert of Rouen, and Mott,—the latter of whom has published an interesting ease in the January numbers of the American Journal of the Medical Sciencees, for 1842 and 1843. The external edges of all such wounds must afterwards be carefully approximated, and immediate union encouraged.

The diagnosis of tumours of this description is seldom difficult—the object being generally observable, especially in damp weather, in the anterior part of the nostril, or occasionally behind the soft palate. I have often known a bend in the cartilaginous septum mistaken for one, and have also seen the thickened Schneiderian membrane supposed to be a gelatinous polypus. In some instances large growths of the kind, in the back part of the nostrils, above the soft palate, have been entirely overlooked for years. I have repeatedly seen soft tumours of the antrum attacked with foreeps, under the impression that the disease was, in each instance, confined to the nostril. One case occurred to myself: there was no swelling in the cheek, nothing to induce suspicion that the disease was not a common nasal growth; the other (occurring in the practice of a very experienced surgeon), was similar in appearance and history: in both as soon as the part projecting into the nostril was removed, and it was ascertained by the finger that the antrum was full of apparently malignant growth, the proceedings were immediately given up. Subsequent experience has led me in several instances to persevere in clearing out the antrum, with the happiest results—the disease having never returned.

I once saw a case of large polypus in the nostrils, under the care of Sir Andrew Smith, late Director-General of the Medical Department of the Army, who was then the principal medical officer at Fort Pitt Hospital. The tumour had been of several years' growth, and projected prominently on the face on each side of the nose. In each nostril a large mass could be seen, and a probe could be passed with ease below and on both the outer sides; but as doubts were entertained regarding the attachments in the middle and above, it was not considered advisable to resort to any operation. Some weeks after the patient died, and my former pupil and assistant, Dr. George William-son, then staff-surgeon, obliged me with an account of the dissection: "The tumour extended from the ethmoid bone to the eondyles of the oecipital, and was also attached to both sides of the septum. Two large pendulous bodies hung down into the pharynx. The turbinated
bones were absorbed, but the mucous membrane which contains them was entire. There was no attachment to the outer walls of the nasal cavity. There was a large abscess in the left anterior lobe of the brain, with an opening leading from it into the nose.”

Plugging the nostrils for epistaxis is often a more troublesome process than might be imagined. The student may practise this on the dead body, and should not neglect to do so. On the living or dead it may be done in this way:—A piece of sponge or rolled lint, something larger than the end of the thumb, having a bit of twine or cord attached to its centre, with the two ends, eight or ten inches long, hanging free, should first be provided; then the end of a common silver probe armed with a long portion of ligature thread should be pushed along the floor of the nostril until it is seen in the pharynx: one end of the thread should now be seized with forceps and drawn forwards through the mouth, while the probe is withdrawn, leaving the other end in the nostril: this thread hanging from the mouth should then be attached to the two ends of the cord around the plug, and these by pulling the nasal end will be drawn along the mouth behind the palate and thence through the nostril, until the plug to which they are attached impedes their further progress, by being arrested in the posterior aperture; now the ends hanging from the anterior opening should be separated: a plug similar to that already used should be laid between them, a noose should be made to keep it close upon the aperture, and a knot being secured, the operation is finished. Sometimes stuffing the nostril in front will obviate the necessity for the posterior plug; but when the latter is deemed necessary it is always proper to apply one in front likewise. There is no additional pain: it acts as a kind of fixed point towards which the posterior one
HARE-LIP.

495

can be drawn, and, moreover, closes the nostril as effectually in front as the other does behind. Both nostrils may be plugged if required in the same manner, and, on the second or third day after, the pads may be removed. Sometimes it will be difficult to dislodge the posterior one, and for this purpose it may be necessary to push a bougie along the passage, or to hook the forefingers up behind the posterior margin of the soft palate. I have sometimes seen a thread left in the mouth attached to the plug to facilitate removal.

It may be found difficult to effect the introduction of the thread with the probe, which will be barely of sufficient length, and if a small flexible bougie is at hand it will suit better; but what will answer best is a piece of curved elastic watch-spring concealed in a sheath something like a common catheter. At the point of the sheath there is a bulb with an eye in it which is attached to the spring, and when this is pushed along the nostril, after the end has been carried into the pharynx, it can be made to project into the mouth in such a way that a thread attached to the eye may be readily laid hold of, or if it is preferred, the eye can now be threaded with a small cord attached to the stouter one on the plug, and the rest of the proceedings can be accomplished in the manner described above. Such an instrument is to be had in the shops, and is represented, as also the posterior plug referred to, in figure 311.

CHAPTER V.

MALFORMATIONS, DISEASES, AND OPERATIONS ON THE LIPS.

The congenital malformation termed hare-lip comes under notice in a great variety of aspects. This deformity consists in one or in two fissures in the upper lip, resembling in some respects the natural angles of the mouth. The condition is found almost only in the upper lip. Doubtless it has been named hare-lip from a certain resemblance to the fissure in the upper lip of the hare; but in the human subject it differs in this peculiar feature that it never is in the mesial line, as it always is in the hare. In man the deformity is always under one or both of the nostrils. If on one side it is called a single, if on both it is called double hare-lip. The fissure may appear as a short notch in some; in general it extends to within a little of the nostril, and often it is continuous with this part: when double it may be of the same size on each side, or there may be a short notch on one side and an extensive one on the other. The substance of the lip in all such cases varies much; in some, it is thick and fleshy; in others, thin and defective in all respects, and the breadth of the gap usually varies in accordance with these characters. There is always, even in the worst cases of double cleft, an intermediate portion of lip, and that may be
broad or narrow, long or short, thin or of the usual thickness of the natural lip. Generally it is deficient in development, being short, narrow, and slender, and it rarely happens that the groove under the columna is well defined. In very rare examples this central portion is so defective as to seem wanting.

In most of these cases, every kind of absurd reason is given by the mother and others to account for the deformity. The common one is that the mother, during her pregnancy, has either seen or heard of a case of the kind, and has possibly been much alarmed or disgusted. For my own part, I put no faith in such views, and I imagine that in most of such cases, there is a partial defect in the upper lip and jaw of one or both of the parents. I have noticed this so frequently, that I fancy I can in general detect the parent of a child thus born by the appearance of the face, and often whilst listening to a mother's story about some conjectural cause for her infant's deformity, I have thought that a glance at her own features in a looking-glass might have given her a more plausible reason for the condition of her offspring.

Hitherto, although there has been much speculation as to the development, or rather the "arrest of development" as the term goes, in malformation of the upper lip and jaw, little attention has been paid to the anatomy of such abnormal conditions when met with in the palpable form in which they come under the surgeon's notice, and possibly the rarity of opportunities of examining the parts on the dead subject may be the reason of this. Since my earliest professional years I have had my attention devoted to this condition, but even yet I feel that my opportunities for anatomical investigation have been very limited. I have dissected the single hare-lip, and have observed the fibres of the orbicular muscle ascend along the side of the fissure on each side towards the nostrils in comparatively slender bulk, and I have also noticed the labial artery expand itself on each side. I have observed, as Nélaton, Chelius, and some others have, that a large proportion of these cases have been on the left side of the lip. I know not why this should be, although possibly it may be from the circumstance that the left side of the body is rarely so perfectly developed as the right. In the instances when the gap has extended into the nostril there has usually been the complication of cleft palate. This, however, is not invariably the case. Sometimes the alveolar ridge is complete, at other times it is defective, and when a gap extends through it, as often happens, then the hard and soft palates are usually defective. Such defects are most conspicuous when the fissure in the lip is double, although even here the gums and alveoli are sometimes perfect. In single fissure, and especially in double, the middle portion is often seemingly larger in proportion than the rest of the alveolar ridge, and sometimes it projects so conspicuously as to add greatly to the unsightly condition of the part. Such a projection is, in a single fissure, exactly one half of what there may be in a double one, and it is remarkable to observe the want of precision in language as applied to this projection by most, if not all
who have written on the subject. In double fissure the central mass is formed of two portions. Figure 312, taken from a foetus about seven months old, shows the defective development of the superior maxillary bones, and the drawings below give the appearances in this central mass in older specimens. Fig. 313 shows the condition at a time

when the deciduous teeth are imperfectly developed, and figure 314 is from a child about six years old, in whom the projection was very conspicuous. In these specimens, particularly in figure 312, it will be observed that the gap in the alveolar ridge is directly under the nostril, that here the superior maxilla is defective, and that there is a fissure in the mesial line, showing that this central portion is composed of two intermaxillary bones, resembling in some respects, the condition of this part of the mouth in many of the inferior animals. It is, however, in so far as I know, not natural to the development of the superior maxilla in man. In a conversation which I once had with Mr. Owen, at the College of Surgeons' Museum on this subject, he showed me a specimen in an adult maxilla with a narrow line of junction similar to that which might be supposed to take place in such a case as is represented in figure 312, but in the instance in question the bone was, in all other respects, perfect. In the young subject the intermaxillary portions are attached by a slender junction to the vomer, which, in some instances, may be cut with a knife, but usually, when it seems requisite to remove the projection as a whole, the surgeon divides the stalk of it, as is displayed in figure 314, with forceps. In cases of hare-lip in young children, when the fissure has been single, and when the projection has been such that it has been deemed necessary to remove it, I have often cut the one half away with the knife, in the line of junction indicated in figures 313 and 314.

In operations for hare-lip, if the fissure be single, the proceedings may be conducted in this way: If the patient is young (an infant) a cloth should be wrapped round the chest, so as to confine the arms; a pillow-case answers the purpose well, as the legs also can thus be secured by slipping the patient into it; then the child should be held
by an assistant, with its head resting, face uppermost, between the surgeon's knees; if he puts on an apron of water-proof cloth it will answer the double purpose of keeping his trousers free of blood, and preventing the child's head from falling too low; a little pressure with the thighs will enable him to keep the head more steady than by any other means: a sharp-pointed scalpel, or a narrow straight bistoury, should then be passed through the lip, immediately below the nose, at the margin of the fissure, and carried downwards, so as to cut away the round edge of the gap and the blunt angle at the mouth; if this slip is still attached at the nostril, it must be separated by the point of the knife, which should then be run down the opposite margin in the same manner, and with the same care that the angle at the lower part is completely cut off; if the lateral portions are closely adherent to the bone they should, either before or after paring the edges, be slightly or freely, if needful, separated, when the margins will be more easily and more accurately brought into apposition, which should now be done by means of needles, such as those described at pp. 52 and 53; the further steps of the operation, as to the application of threads, cutting the needles, removing them, and for the after-dressing, being such as have already been described in the Chapter on Sutures, at the commencement of the volume.

A person of older growth may be laid on a couch, or a sitting posture will be equally convenient; and in the latter case the surgeon may stand behind or in front of the patient, as he may choose. I myself prefer the former position, being thus less exposed to the spluttering. On all occasions the knife should be introduced at the part nearest the nostril, for the lip will thereby be kept perfectly steady as the instrument is carried downwards. Sometimes, to prevent hemorrhage, the facial arteries are compressed as they pass over the margins of the lower maxilla, or, what perhaps is better, the margins at the angle of the mouth are grasped between the thumb and forefinger by the surgeon or an assistant, as may be most convenient, and thus, whilst the parts are kept steady, the labial arteries are prevented from bleeding. It is seldom, indeed, that the hemorrhage from these gives any trouble; no time need be lost in attempting to suppress it by cold or by ligature; for if the lowermost needle is passed in close contact with each bleeding orifice, the pressure of the opposed surfaces will effectually stem it. Two or three, or sometimes four needles (as I have found necessary) will be required, according to the length or depth of the wound.

Some operators have chosen scissors for cutting the edges of such fissures, and others have used a piece of wood or horn, on which the lip has been laid, and pared with a bold stroke of the scalpel; but for my own part, I prefer the mode above recommended. Unless the lip is transfixied, it will be difficult to keep it steady in any other way: the action of the orbicularis, the levatores, and the zygomatici, is often such as to pull the lip from between the fingers, scissors, or off the piece of board; whereas, if the bistoury is dexterously used in the manner described, the action referred to rather adds to the facility
HARE-LIP.

with which the incision can be made, by drawing the parts in some degree against the sharp edge.

The dotted lines in figure 315 point out the course of the incisions in an ordinary case of this kind,—a single fissure. Occasionally it may be necessary to extract one of the teeth, or perhaps two, to permit the edges being brought together; and in rarer instances a small portion of the jaw requires to be removed, with the knife or cutting forceps. If this latter step be taken with young children, a heated iron should be in readiness, as possibly a vessel in the osseous texture may bleed more freely than might be desired in such patients; but it should not be used unless the bleeding shows no disposition to stop.

In double hare-lip the lines of incisions, such as may in ordinary cases be required, are indicated in figure 316; but there will often be occasion for the surgeon to exercise his ingenuity and skill. Sometimes the centre slip is so broad that, instead of such an acute angle as represented in the drawing, a portion of the red margin below may be left; or possibly it may be so narrow and so thin from before backwards, that it may be well to remove it altogether; at other times this slip may be advantageously carried upwards and slightly backwards, so as to increase the length of the columna, which is often, in this species of malformation, so short as to add greatly to the flatness of the nose,—an addition to the deformity sometimes very conspicuous; in other instances it may be cut in the form of a wedge, which, while it separates the lips above, does not extend so far down as to prevent them from coming into contact at the mouth. The slips in the double fissure are usually so flat, that the nose can seldom be made such a prominent feature as when there is only a single gap; but even in the latter it is occasionally difficult to make both sides symmetrical. Some authorities have recommended that in the operation for double fissure only one should be operated upon at a time, and that the second proceeding should not be attempted till the lapse of some weeks at least; and whilst giving sanction to this practice as advisable in many instances, I cannot but say, however, that the plan of closing both on the same occasion is in general decidedly to be preferred.

Some surgeons, unwilling to sacrifice this intermaxillary prominence, have applied pressure for weeks or months until it has been forced into a more favourable position, while others have pushed it backwards with flat forceps with an effort sufficient to cause fracture.
This latter practice has been followed by Gensoul, and it seems reasonable to adopt it, if the case appears a proper one, in preference to removing the portion altogether. Possibly the bit of bone might bend into its proper position, but should there be fracture I imagine that no evil would result. I feel bound to state, however, that after trying this plan on several occasions, the result has not been satisfactory, and I have been obliged after all to remove the projection. The portion of lip covering this projection might be first dissected towards the columna or not, as should seem most desirable.

In many instances, whatever pains the surgeon may take, there is some risk of a notch being left, which for ever after shows a conspicuous defect. This figure (317) represents a common appearance after puberty, when the condition is neglected till this period; and figs. 318 and 324 show notches such as above referred to, although in reality not so great as often met with. To prevent such a notch, and make the operation more perfect, it has been proposed to carry the lines of incision through the margins in the direction marked by the dotted lines on figures 319, 320. The semicircular line has been claimed by Mr. Syme, and the line with the angle at the upper margin of the prolabium is usually attributed to Malgaigne. I have tried both plans frequently, and can bear witness in their favour as enabling the surgeon, both to do away with the notch above alluded to, as well as to give that length or depth to the upper lip, which is often so deficient. Neither of these lines, however, will be of much avail unless the margins be freely pared, and in all the operations for
hare-lip which I have myself performed, whether single or double, I have never had reason to regret having cut away too much, but often wished afterwards that I had not been so sparing of the margins. This is mentioned for the sake of the young operator, who may probably suppose, as I myself did, that he will not be able to bring the edges in sufficiently close apposition: on this score however, he need be in no dread. I suppose it perhaps impossible to obviate the notch in all cases, as, in consequence of the contraction of the cicatrix in its long axis, the free margin of the lip is sometimes elevated, during the lapse of weeks after the operation, in a way which I cannot tell how to prevent. This defect is very conspicuous in figure 324, although, when the operation was performed, the margin of the lip was probably below its proper level. If the gap has not been very wide, and the needles are properly used, there is no necessity either for straps or bandages to keep the cheeks forwards; and though occasionally a slip of plaster may be advantageously applied after the removal of the pins, to support the tender adhesions, even this may be dispensed with in many cases. It will, however, in general be judicious to protect the wound for a time in the latter way, or, what answers better, the threads should be covered with collodion, which may be spread over them and the skin at the same time, so that they shall not fall off for several days after the needles are withdrawn.

In general there is little trouble with single hare-lip, although every now and then, either from scantiness of tissues or from some more incomprehensible cause, the union is not accomplished. In some such instances, trusting to the granulations adhering, or sometimes scraping the surfaces anew, I have introduced fresh needles, and been well pleased with the result, but on other occasions union has not occurred in spite of all my efforts. I had tried most of the plans proposed to obviate this mishap, but had not thought any superior to that of applying straps of adhesive plaster from side to side to keep the raw margins together. Many years ago, however, a simple contrivance was brought under my notice by a very ingenious mechanic, Mr. Hainsby, who had designed it to apply to the face of his own child, who had already been operated on twice unsuccessfully,—
one by the perfect hand of Mr. Liston. The apparatus will perhaps be best understood by reference to figure 321. It is essentially composed of a semicircular spring, which, padded at both extremities, presses gently upon the cheeks so as to push each towards the seat of fissure, and take off the strain upon the needles in the site of the operation. This spring is retained in the proper position by straps, which are adjusted over the cranium, as seen in the sketch. An account of this instrument was published in the Medical Times for 21st Dec., 1850, and I was then so much pleased with it that I have rarely performed the operation since without using it. Long prior to the period referred to, my friend, Dr. Dewar of Dunfermline, had advantageously applied a similar contrivance to several bad cases of double hare-lip, which came under his care. In a communication which I had from Dr. Dewar on this subject, I was struck with the simplicity of the circumstance which gave rise in his mind to the idea of this instrument. Whilst musing as to how he should deal with one of the complicated cases in question, which had just come under his care, he happened to lay his thumb and fingers so upon his cheeks as to cause the upper lip to pout, when suddenly the idea struck him that he might gain a similar forward movement by such an elastic spring as is above referred to. The happy idea bore ample fruits, as may be seen from an interesting paper of Dr. Dewar's on the subject in the Edinburgh Medical and Surgical Journal for July, 1830.

Although I do not deem this apparatus absolutely necessary in all instances, it seems to me so useful that I rarely dispense with it. Since I first used it in 1850, I have operated on nearly 400 cases, in all of which I have been highly satisfied with the results. I am aware that in some of these instances it was not specially required, but in many of them the result would without it have been very doubtful, and the treatment at any rate very troublesome. I regret that I had not known such a plan at an earlier date in my practice, as it would have saved me much trouble and anxiety. The apparatus often causes oedema on the face, probably from pressure on the facial veins, but although this has affected the features for the time, I have never known any evil arise from it.

In the Medical Times for 2nd November, 1850, a case of hare-lip of the worst imaginable kind is related as having been successfully treated by me, by the ordinary method without any support on the cheeks, and I now feel certain that if such an apparatus as that above alluded to had been used, much of the anxiety connected with it would have been averted. Since then, among numerous instances of an
ordinary kind, both single and double, I have treated many nearly of equal difficulty, and attribute much of my success in these cases to the instrument in question. Figures 322 and 323, give front and profile views of one of these patients prior to treatment, and figures 324 and 325 give similar views after the operation. It will be observed here that figure 324 represents the line of junction in the middle, and from this an inadvertent observer might take it as a proof that the fissure had been in the mesial line, but figure 322 shows the contrary, and the operation in this instance was an example where the mesial slip, instead of being retained in the lip, was used to make the columna. Had this part been reserved for the lip, the tip of the nose, as may be judged from figure 323, would have been drawn down in an unseemly manner.

When the central portion of skin is reserved to form the columna, its apex is made raw, and the surface is applied to the raw surface at the upper end of the lateral parts. It is usually cut like a wedge and held in its place by the uppermost needle. Occasionally union does not occur, and the result is for a time rather awkward and possibly annoying to the young surgeon. But in such a case, unless the skin intended for the columna is very short, there is no great difficulty in securing union at some future date. The tip of the skin and the upper end of the cicatrix being made raw again, the surfaces can be held together by a fine needle or a stitch or two (of silk or wire), and if care be taken that the patient’s health is good at the time the result is usually satisfactory.

The period of life which I think very eligible for these operations is in earliest infancy, provided the health seems good. If the child is allowed to grow up, he is usually very unmanageable until after the age of puberty; but if possible the malformation should always be put right before this time, as there is a better chance of the jaw and nose assuming a good shape than when they have arrived at their full development. Indeed, there are so many advantages besides these,—as to speaking, appearance, &c., that it is wonderful why any surgeon can recommend delay in such cases after the first or second year of life. Much has been said as to the propriety of letting the period of dentition be over. Provided the child seems well I see no reason for delay on this account. I have never, in a single instance, seen any evil arise which could be traced to this cause. Certainly, if a child seemed to suffer greatly during dentition it would be unwise to add to its distress by such a proceeding; but, with this exception, I do not consider that there is any just reason for delaying an operation; I have myself operated very frequently within the first three weeks, and
in some of these instances seen the child take the breast readily, with
the pins still in the lip. It has been the custom with some surgeons

to operate at the earliest possible date. Dr. J. Mason Warren has

operated on infants only a few days old, with perfect success. Pro-
tessor P. Dubois read before the Academy of Medicine of Paris, on
27th May, 1845, a paper on this subject, and referred to seven instances
which had come under his notice where the proceeding had been re-
sorted to successfully within the first few days after birth; Malgaigne

and many others have followed a similar practice, and my impression
is, that it is one now more frequently followed than heretofore. Mr.
Henry Smith has operated successfully on the fourth day, and an
interesting example has been recorded in the Medical Times, vol. xxii.
p. 383, by Mr. Bateman of Islington, of a successful operation four
hours after birth. From all my reflections and experience on the
question, I am more than ever disposed to recommend a very early
operation. Most of my patients have been under three months (some
of them only eight and ten days) old, and these cases, as well as expe-
rience derived from other sources, induce me to recommend the earliest reasonable date in all instances of the kind, unless there be
some apparent indication not to interfere. I have frequently observed
that the younger the infant the more satisfactory was the union within
the first few days. Throughout the whole of my practice, I have seen
three deaths from this operation; one in consequence of erysipelas of
the face, the other two seemingly from sinking induced by the shock
of the operation. These cases, however, do not lead me to alter my
views regarding the general proposal here inculcated. An erroneous
impression (as I suppose it) prevails that children are remarkably
subject to convulsions while undergoing operations; and this is often
urged as a reason for not interfering with hare-lip in early life.
Doubtless convulsions have occurred in some of these cases, but similar
effects have been produced in the adult, and by less formidable means,
too. Sir Astley Cooper has referred to several examples of the kind,
yet I imagine they must be rare indeed. I once asked the late Dr.
Abercrombie, of Edinburgh, the results of his experience on this point,
and he could not bring a single instance to his recollection where
convulsions could be fairly attributed to an operation. In my own
opportunities I have never seen a case of the kind, although I
have performed much more severe operations on newly-born infants
than that for hare-lip could possibly be,—as in cases of imperforate
anus, where the gut has been deep, and when the proceedings have,
in almost every respect, been equally severe as if for the
extraction of a stone from the bladder. Indeed, from my own
experience, I am now strongly of opinion that there has been
some mistake in regard to the term "convulsions" in such examples.
I repeat, that I have never seen an instance of the kind. I have
occasionally been told by nurses that an infant, on whom I had
operated recently for hare-lip, was in convulsions; but instead of
finding this to be the case, I have observed remarkable quietude,
and everything quite the reverse of convulsions. In such infants
there has been a sleepy, half comatose condition, not at all resembling convulsions.

In the course of my experience I have met with cases of congenital fissures in the lips which, while remarkable in themselves, and interesting in various respects, have appeared to me inexplicable on any of the assumed causes of the ordinary hare-lip. For instance, the following case came under my care at King's College Hospital in 1853. On the face of an infant there was a fissure on the left side of the upper lip, resembling that usually called hare-lip, and on the right side a fissure extended from the angle of the mouth upwards and outwards, as far as the malar bone, having no communication with the nostril. The gum and front part of the antrum, covered by mucous membrane, were apparent, and there was some slight depression in the front wall of the antrum. To add to the remarkable appearance of the face, the lower eyelid on the left side was defective, as if it had been torn and taken an adhesion to the lower part of the conjunctiva of the eyeball, above which point there was such opacity of this membrane as seriously to affect the cornea. Figure 326 gives an outline of the malformations in this case, and figure 327 shows the appearance some years after these fissures were closed, by paring the edges and using the twisted suture. In as far as I have been able to make out, this case was unique in the records of surgery. A notice in the Lancet for 14th August, 1857, is made of a case of fissure in the cheek, in some respects resembling this instance, by Mr. Thomas Wakley, at the Royal Free Hospital.

Within the last few years I have met in private practice with two cases, which, equally with that above referred to, set aside the ordinary theories as to the cause of fissure in the lip. The accompanying sketch (328), gives an idea of the condition in these cases. The angle of the mouth extended horizontally to the front margin of the masseter. When
the profile was looked at, the mouth seemed to extend so far back as to
give force to the expression which was used in regard to one of these
cases—that the child's mouth was like that of a pig! Whether this was
the condition of the mouth of the celebrated lady with the pig's face,
exhibited some seventy years ago, I cannot say, but certainly the
fissure in these infants gave some resemblance to the idea. There
was a remarkable circumstance present in each of these cases: the
tragus was drawn down on the side of the face, and rested half an inch
below and in front of its usual locality. In one instance the tragus
seemed lost or involved in a kind of cicatrix, and in the other, as
represented in figure 328, it was prominent on the cheek, as if it
had been torn or cut from its ordinary position and stuck on its
new site where it had become adherent. These cases were easily dealt
with, by an operation analogous to that for hare-lip. They are the only instances of the kind
I have ever seen, and I do not remember having read of any like
them.

Fissures in the lower lip are very rare. I have seen only one
instance of the kind. This figure (329) was displayed in my lecture
on this subject at the College of Surgeons in 1864. The thick tissue
or substance on the right side was cut away, the edges of skin were
pared, and the gap was satisfactorily closed by twisted sutures, as for the
operations above described. In as far as I know, the case is unique.

Various kinds of tumours are found in the lips. Among the most
remarkable are those examples of aneurism by anastomosis so fre-
quently met with in these parts. Some of them are highly vascular,
and must be touched with a knife with great caution, particularly
when of large size, and when both arteries and veins are much dilated.
Indeed, in general it is best to try some of the other modes of treat-
ment in preference to the knife, particularly at first. If by stimu-
lating or coagulating injections, issues, caustics, or moderate use of
ligatures, the disease can be arrested or obliterated without much loss
of substance, it will be better than cutting away any part of the lip at
once. If after a cure the lip seems redundant, a wedge-shaped por-
tion, horizontal or perpendicular as shall seem best, may then be cut away, so as to bring the part as near as possible to perfection. Such a tumour as this (fig. 330) is easily destroyed by twisting ligatures round it to cause it to slough. I have even dissected some such tumours away without remarkable bleeding or loss of substance; but when the whole thickness of the lip is made up of enlarged vessels, forming a prominent swelling and great disfiguration, the ligature or knife must be used with caution, for fear of taking away more than is requisite. In some cases involving the whole thickness of the lip I have used subcutaneous and sub-mucous ligatures of thread or wire with great effect. After obliteration of the vessels in some of these swellings, I have known contraction go on to such an extent that there was no need to remove any part of the lip or remaining part of the disease.

Cysts are by no means unusual on or near the lips. These are close upon the mucous membrane. They contain a light yellow glairy fluid, not unlike fluid honey in appearance, and are probably obstructed mucous follicles. It is rare to see more than one in the same individual. When punctured they are apt to fill again, and it is best that the sac should be taken out. I have known the sac ultimately become a solid tumour, which caused some disfigurement.

Moles sometimes become so large and conspicuous close upon the lips that the surgeon is requested by the patient to remove them. They may be destroyed by caustics or ligatures, but sometimes it may be best to remove them by knife or scissors.

Indurations, which can scarcely be recognised as any of the known kinds of tumours, sometimes form on the lips, particularly the lower one, and often in the course of time these ulcerate and show a tendency to increase. It is rare for these sores to heal and leave a healthy soft tissue behind. More frequently they assume the characteristics of open cancers. The form of this disease found under such circumstances is that to which the term epithelial has been applied. It is not considered of such a malignant kind as some others, and certainly operations for its removal are more successful here than for cancer in most other parts.

Such conditions as those alluded to are usually found on the lower lip—the upper is rarely thus affected—and they may be near the corner of the mouth or towards the centre,—sometimes so small that
they might be covered with the tip of the finger; at others involving nearly the whole of the free margin. Incisions of this shape V will generally effect the removal of the whole disease, which will be comprised within the two lines: the surfaces can afterwards be brought accurately into apposition, and retained by one or two twisted sutures. Here I also prefer the scalpel or bistoury, with which I generally transfix the lip, and cut towards the free margin, although on this latter point I am not so particular as with the hare-lip, for the fingers suffice to keep the parts steady. The labial artery should be secured by the uppermost needle in the manner recommended in the operation last referred to. When, however, nearly the whole lip is affected, as is here exhibited (fig. 381), if such incisions are made as those just alluded to there will be difficulty in bringing the edges sufficiently close, and although it is wonderful how much the soft parts stretch on these occasions, it often answers well to cut the diseased surface away by an incision parallel with the margin of the lip. The part should be seized between the forefinger and thumb of the left hand, when the bistoury should be entered at one side and carried along between the sound and diseased textures until separation is effected. Perhaps the labial artery at each end of the wound will require a ligature, or probably torsion may be serviceable here: possibly, however, the stitches will suppress all bleeding. These should now be introduced by passing a fine needle (p. 34) from the margin of the skin to that in the mucous membrane, and as each thread is tightened the two textures are approximated, so that a line of junction will be formed in the centre. Three, five, or seven stitches of the interrupted suture will probably be required, and if these are applied carefully union will be much more rapid and satisfactory than by allowing the cut surface to heal by granulation. At first, and for several weeks perhaps, the gap may appear considerable, but ultimately it will be far less conspicuous than might be expected. In instances of small ulcers, when the hard circumference has not been extensive, I have sometimes scooped off the part in this way, and afterwards the mark has been less observable than in those where double lines of incision have been made as described in the preceding page.

Whilst I caution against heedless rashness in resorting to the knife in every case of suspicious character, I cannot but allude to the fearful consequences of unnecessary delay in such instances. In some respects an operation for a malignant disease must be considered as a last resource;—it is, indeed, all that the surgeon can do, but the phrase must be taken in a very different sense in such cases from that in which it is used with reference to amputations or the separation of
benign growths: for as we know of no remedy but the knife for the removal of these fatal affections, and that too before the neighbouring parts, such as the lymphatic glands under the jaw, become contaminated, the sooner an operation is resorted to the better. For further remarks on such subjects I must refer to the Chapter on Tumours, and shall here only state, that whilst I have seen numerous instances where both patient and surgeon have had reason to regret that a portion of the lip had not been removed at an earlier period, I have never seen an example where it could be said that an operation had been unnecessarily performed. In one person who had an open sore on his lower lip on a hard basis for about two years, the surface cicatrized under the use of nitrate of silver:—six months afterwards, and while the part still remained whole, I was asked to remove a tumour from below the angle of the jaw, which proved to be a cyst containing a serous fluid: the disease seemed completely removed, but in less than two months a scirrhous hardness formed around the cicatrix, and ere long the patient died with great swelling and cancerous ulceration, such as are but too frequently seen in those from whom the verge of the lip has been removed after too literal an application of “the last resource.”

Sometimes the lower lip is so largely affected in these instances, and the portion requiring removal so great that the saliva and mucus escape freely through the gap, and a most unpleasant condition ensues. Possibly some previous affection, such as the cancrum oris in children, may have left the chin in this state. The upper lip is also sometimes thus defective, and occasionally the mouth may be so altered in shape and size—the orifice being either greatly too large or the reverse, that a patient will readily submit to any surgical interference which shall promise improvement. Portions of skin have been transplanted from the arm, from the upper part of the neck, or from the cheeks, and fitted into surfaces properly adapted for their reception; but several examples of such proceedings which I have observed have not impressed me favourably with their advantages. The skin is much more apt to slough here than in the reparation of the nose, and therefore, should such attempts be made, the attachment of the flap must be left as broad as possible. As each case requiring such interference will have characters peculiar to itself, no set rules, other than those in accordance with the principles of surgery, can be laid down for such proceedings. I may, however, refer those who are much interested in such matters to the works of the Professor of Bologna (Taliacotius), who seems to have been almost equally ingenious with his contrivances here as for those with which his name is so generally associated, and in an especial manner to the publications of Serre, of Zeis, and of Professor Paneast—a gentleman who has distinguished himself greatly in modern times by his plastic proceedings both here and in other parts of the face. Mr. Syme has performed some ingenious operations for the restoration and improvement of the lower lip, and the late Dr. Richard Mackenzie earned distinction by similar proceedings. I may here refer those who wish the particulars of such cases
to the London and Edinburgh Medical Journal for 1847, and 1851-52. The papers by my late friend Mr. T. P. Teale, of Leeds, on the same subjects, in the Medico-Chirurgical Transactions for 1855, and in the Medical Times for June, 1857, are well worth notice. In distortions similar to figure 332, Mr. Teale has displayed remarkable ingenuity in constructing a new lower lip from the sides and lower part of the face. Such cases are by no means unusual, as the result of burns and scalds in early life, and the example depicted is one of the worst I have seen. The poor lad whose face is here portrayed, was burnt almost to death. His eyes were destroyed, and besides the destruction of other features, his mouth was left with the under lip everted, and its margin attached to the upper end of the sternum. In this instance there was no use meddling with the eyelids. Sight was gone and could not be restored, and there was no special complaint otherwise. There was, however, a constant dribbling of saliva from the mouth, which caused great distress. To remedy this I dissected the lip from its abnormal attachments, and by careful attention in dressing, kept its free margin so much in the natural
position as to get a cure with the lip as represented in figure 333. These two figures (334 and 335) give further illustration of this subject. A girl was left in the condition represented in figure 334, and by a similar dissection and subsequent dressing was finally left as in figure 335. I have since repeated this operation on several occasions with excellent results, and am of opinion that, either by the plans recommended by Mr. Teale, or if the parts were dealt with in accordance with the principles laid down in this volume, on the subject of scalds and burns, and the examples referred to at p. 261, great good would result.

In one instance I succeeded in the following manner in improving a young man's appearance whose under lip had in early life been destroyed by ulceration. Two central incisor teeth which projected forwards, were removed, and then a scalpel was carried close upon the periosteum of the chin so as to separate the cicatrix and the neighbouring parts from the bone: next I cut away the cicatrix by incisions of this kind, brought the edges into contact by stitches of interrupted suture, and thus covered over the gap which formerly existed, by bringing the soft parts from each side to supply the deficiency. The result was not altogether so perfect as could have been wished, as a part of the wound at the mouth fell open again; but, upon the whole, I was more sa-
tisfied with what had been done than if a flap had been brought up 
from the neck. I have subsequently performed a similar operation in 
another case of the like sort, but the result did not come up to my 
expectations.

I was onee asked if I could lessen the lips. A young man in 
whom these features were somewhat too prominent, importuned Sir 
George Ballingall and myself to do something for him, but we strongly 
advised him to rest contented. To this, however, for reasons which he 
did not choose to explain, he was not at first inclined, although he 
afterwards followed our advice. It was my intention to have cut a longi-
tudinal portion of a wedge-shape out of the thiekened parts, immediately 
within where the lips join, about an inch and a half in length, a quarter 
of an inch or a little more in thickness at its middle, and tapering to 
each end: then I should have used stitches of interrupted suture, and 
doubt not that the patient would ultimately have been pleased. Such 
a proceeding has occasionally been restored to, and I have recently 
had a very satisfactory case of the kind; so any one particular about 
his personal appearance, and anxious for a bonne bouche of the sort, 
might certainly be gratified, although I should not in general be in-
clined to recommend any interference. There is a very unseemly 
malformation called double-lip, which is characterized by a remark-
able projection of the mucous membrane of the upper lip when the 
person who has it laughs, which may be very easily and effectually 
remedied by a proceeding similar to that above referred to. Boyer 
was, I believe, the first to practise such an operation, and considering 
the frequency of the double-lip I often wonder that it is not more 
resorted to.

CHAPTER VI.

DISEASES OF, AND OPERATIONS ON THE TONGUE, THROAT, EARS, 
PALATE AND MOUTH.

Various operations may be required on and about the tongue. Among 
the latter I may allude to division of the cranium in children. Occa-
sionally this part seems so short as to impede the free movement of the 
organ, and, usually when the child is at the breast, the nurse requests 
the operation to be done. For this purpose the common surgical 
scissors (p. 35) should be applied to the fold of mucous membrane 
close upon the symphysis: a division about an eighth of an inch will in 
general suffice, and there is no necessity for approaching the tongue 
so as in any way to endanger either the ramine veins or arteries. 
When the child is touched it will cry, and at this time, when the 
tongue is raised, the scissors can be used. The forefinger of the
surgeon's left hand may be introduced and held against the lower part of the apex of the tongue to put the franeum on the stretch, and also to prevent the mouth closing.

I have known the ranine veins punctured with a lancet in instances of cynanche in the adult,—a useless practice in my opinion.

An incision or puncture may sometimes be required in examples of obstruction of one or other of the salivary ducts. That of the parotid is rarely, if ever, thus affected; but those under the tongue, especially that of the submaxillary gland, constituting the condition termed ranula, may require interference. Sometimes a hard concretion forms in one or other of these ducts. I have one in my possession the size of a kidney-bean; but more frequently the swelling, which is always more or less conspicuous, is occasioned by a collection of glairy straw-coloured fluid: in either instance the point of a lancet or bistoury will make way for the escape of the contents of the dilated duct, and afterwards, in all probability, the saliva will keep an opening for itself as it continues to flow into the mouth. Should this close and the swelling return, means must be taken, by cutting away a portion of the sac, and by inserting dressings into the wound, to prevent such an occurrence in future.

I have left the preceding paragraph much as it has appeared in previous editions. Now, I question if the salivary ducts are ever thus affected, and I feel convinced that the prevailing opinion as to the collections of glairy fluid above referred to being in these ducts is erroneous. It has fallen to my chance to sec many cases of this kind, and I have in recent years repeatedly satisfied myself that the fluid is not connected with the salivary ducts. In instances where the cyst has been as large as a hen's egg, I have pushed a probe along the ducts of the sublingual and submaxillary glands, so as to be certain that there was no obstruction, and in such cases I have noticed the saliva flow from the proper ducts without any change in the sac of fluid. Besides, I have opened these cysts and removed them with forceps and an occasional touch of the knife, just as is done with cysts loosely connected elsewhere. I am disposed to think such tumours are analogous to those met with (perhaps more rarely) in the lips, as referred to in the preceding chapter, and that they are collections of inspissated mucus in an obstructed, dilated, and thickened follicle.

I have known such cysts project almost as prominently in the neck under the maxilla as in the mouth, where they in some instances push the tongue to the opposite side. In such examples the best practice is to puncture the cyst through the mucous membrane below the tongue, then to squeeze out all the fluid by gentle pressure, and to repeat the puncture, should it accumulate again, ere the swelling attains its original size. Perhaps on a third occasion, cutting away a portion of the sac and dressing, as above recommended, may be resorted to; but it will be better, if practicable, to remove the whole sac. In cysts of smaller bulk I should take away the cyst at once, if there were no good reason for the contrary; and such a practice I deem far
superior to any other, especially the seton or caustic. The gap where the cyst has been will speedily contract and close.

I once met with a cyst in this locality which gave a deal of trouble in its extraction. Figure 336 will give some idea of its magnitude. The tumour, when it came under my notice, had been growing for many years. The man was about forty; his condition was very distressing: he could neither close his lips, masticate, nor swallow with comfort, and, without an effort, he could scarcely breathe excepting through his nostrils. There was a tumour, the size of a fist, situate between the under and front part of the tongue and the base of the lower jaw. It extended downwards upon the hyoid bone, and projected prominently under the chin; it pressed upwards, so as to push the tongue against the soft palate, and fill the mouth, as represented in the drawing,—for the mass seen within the teeth in the figure is chiefly the tumour and portion of the lower surface of the tongue. It was with difficulty that the patient could show the upper surface of this organ. The lower incisors were thrust forward and slightly separated from each other by the continued and gradually increasing pressure of the swelling. The mass was a little fuller on one side of the mesial line than on the other. The skin and mucous membrane over it were healthy, and, notwithstanding its particular position,—being in a manner hemmed in on all sides, it did not appear to me fixed or attached beyond the possibility of removal. I had an impression that it was of the nature of those above referred to, the contents being probably more consolidated and the cyst much thickened, so as to prevent the perception of fluctuation.

In my plans for removing this tumour, I fancied that by an incision in the mouth the contents of the cyst might be evacuated with ease, and that I might then pull or dissect it out with little trouble. Contrary to my expectation, however, the cyst contained a thick curdy material, such as is found in atheromatous tumours of the scalp, which was so firmly imbedded in the sac, that it was squeezed

Fig. 336.
and scooped out with difficulty. To facilitate proceedings I made an incision into the cyst through the skin beneath the lower margin of the jaw, and partly in this direction, partly through the mouth, succeeded in getting rid of the contents; but the thick bag remained, and there was still considerable swelling. Dreading to leave a sac so large and thick to the certainty of a violent inflammation resulting from what had already been done, I resolved, instead of making only a partial excision, as had originally been intended, to attempt the extraction of the whole cyst. This was accomplished by extending the wound in the mouth, but not without great trouble and loss of blood. The sac was so amalgamated with the surrounding tissues at most points, that a free use of the knife was required, yet no large vessel was cut, and there was no occasion for ligatures.

The patient was carried to bed rather exhausted, and about eight hours after I was called to see him, in consequence of continued oozing from the wounds in the mouth and in the neck. I found the swelling as great as before the operation, although, after the removal of the sac, the parts were soft and flaccid. The cavity was full of clotted blood, which I scooped and squeezed out, to permit eontraction of the surrounding tissues. Cold water was freely used, and happily the bleeding ceased. A little suppuration ensued in due time, and ultimately a healthy cicatrix formed, when the patient could elose his mouth and masticate as well as if no such disease had ever been present. I saw him years afterwards in perfect health.

This was the only instance in which I had met with a tumour of the kind in this locality, until about five years ago, when a girl about twenty years of age came under my care at the Hospital, under almost similar circumstances. Here I treated the ease more like an ordinary abscess. The cyst was opened, first by the mouth and latterly by the neck, and having suppurred, was treated like a common abscess. The result was highly satisfactory, and gives reason to think that the ease above described might have been treated in a similar way.

The real ranula consists of a hard concretion in the duct of the sublingual or submaxillary gland—a deposit doubtless from the fluids secreted by these glands or ducts, such as is thus represented (fig. 337). These, when they attain such a size—I have seen them both larger and smaller—give rise to much continued irritation. Their removal is often a difficult process. In the submaxillary region the surgeon naturally cuts with hesitation for fear of the artery, which, if divided from the mouth, where the incisions should be made, might give much trouble. An incision should be made through the mucous membrane at the side of the tongue, over the concretion and into the duct, and the scoop end of a director will enable the operator to turn it out of its place. Where the surface is rough, it does not always turn out readily at once, and I have sometimes seen them break, so that they had to be extracted in fragments.
I have seen several instances of remarkable swelling about the tongue which I could not account for from any previous experience. In one of these there was considerable swelling of the organ, copious flow of saliva, difficulty of speech, and remarkable difficulty and pain in deglutition. These features and considerable œdema about the mucous membrane under the tongue, led me to suspect abscess about the back part of the organ, but a close examination failed to detect the presence of matter. During increased suffering the patient suddenly became aware of the presence of additional fluid in the mouth, and soon perceived a quantity of matter which he supposed had come from about the root of the tongue. There was speedy relief, and the result was all that could be desired. Some time after I saw a case very like this one, and anticipated a similar end; but the patient, a strong middle-aged man, died from exhaustion without any discharge of matter. In both of these instances the palate, uvula, and tonsils were not involved, so that there was no appearance of ordinary cyananche. In August, 1856, I had to travel some distance to see a gentleman who had been unable to speak or swallow for several days. The pain at the root of his tongue was sufficient to deter him from making efforts of the kind. On careful examination I fancied there was swelling and some fluctuation at the back part of the tongue, near the epiglottis, and, under the impression that matter was there, I made a puncture with a slightly curved lancet (figure 70, p. 84), and let out a quantity of foetid pus. The relief was so rapid, that the patient could swallow and speak audibly in a few minutes after. Such cases are, in my experience, very rare.

Sometimes it is necessary to remove portions of the tongue for supposed scirrhous indurations or cancerous ulcers, but before resorting to such mutilations, the effects of local remedies and constitutional treatment in such cases will have been tried. The mucous membrane here sympathizes in a remarkable manner with functional derangement of the digestive organs, and often, when least expected, a change of treatment will avert all cause of alarm. If the apex of the tongue is to be removed, it should be protruded between the lips, seized with hook-beaked forceps and divided by scissors or knife. The bleeding will seldom prove troublesome. If, however, the separation is required towards the middle of the organ, the dorsal arteries or the ranine may prove so, and a cautious surgeon might prefer ligatures to the cutting instrument. He may proceed thus: The point of a needle in a handle (p. 35), armed with stout cord, should be pushed through the tongue behind the seat of disease, and when the ligature at its eye is laid hold of by the fingers, the instrument should be withdrawn: next the cord should be cut in two, and then a firm noose can be tied on each side, so as to cause the parts included to slough away. Ligatures may be applied to the side of the tongue in a similar manner, but the process is a little more difficult perhaps, particularly as regards fixing the threads. Here, as occasionally with the apex, it suits well to make notches with the knife or scissors to let the threads sink into the substance of the tongue. I have sometimes removed large por-
tions of the organ with a free application of cutting instruments, and have experienced no great trouble from the divided vessels, yet it would be well on all such occasions to take the probability of such an occurrence into consideration. Every surgeon of experience must have felt the trouble and difficulty of applying ligatures to the tongue after accidental injuries, whether for the purpose of securing vessels or approximating the edges of wounds. In one instance I secured the dorsal artery by passing a tenaculum deep into the muscular fibres and casting a noose of strong thread under the convexity of the instrument. The vessel had been wounded by an upper incisor, and had bled for ten hours.

M. Jules Cloquet removed a portion of the tongue through an incision between the symphysis and the hyoid bone, and Mr. Arnott has related (Med.-Chirurg. Trans., vol. xxii.) an instance, in which, by a similar proceeding, he successfully separated a very large part of the organ. A free opening was first made in the skin and other textures, and then ligatures were applied to cause strangulation and sloughing.

Since the last edition of this work was published, surgery has been as active with reference to diseases of the tongue as in other departments. In my earliest recollections I can think of no part of the body where surgeons were more chary of cutting than in this organ. In 1848 I felt impelled, through a sense of duty as well as friendship, to use the knife more freely than I had ever done before. At that time my friend, Professor John Reid, of St. Andrews, well known for his brilliant physiological researches, was the victim of induration and ulceration of the tongue. Unhappily much time was lost in the consideration of his case, and the disease was allowed to extend largely. When all hope was given up, either from medicine or time, Professors Simpson and Bennett, of Edinburgh, urged an operation. The patient assented, and I removed more than one-half of the organ, the disease being chiefly on the side. The knife was carried past the mesial line. Dr. Reid was possessed of great moral courage and physical endurance, and we trusted largely to him to give every facility to apply ligatures should they be required. The bleeding for a minute or two looked formidable; several vessels were speedily secured, and there was no further trouble in this respect. The wound healed with rapidity, and the patient made an excellent recovery. The mutilation seemed trivial, speech was but little affected, and the change to vigorous health from great exhaustion was specially remarkable. Unfortunately, within the year after this operation the disease came again, and produced a fatal end. This case had a strong effect on my surgical mind; more cutting had been done than I ever had seen or heard of, the bleeding was less alarming than I had anticipated, and the temporary recovery was beyond expectation. It may be presumptuous in me to fancy that this case produced great change in operative surgery in cases such as are now under consideration, but certain it is that in a few years after surgeons used liberties with the tongue by the knife that had never been dreamt of. With myself, the
knife was in frequent play, and in time Mr. Syme, who had strongly objected to the operation above referred to, removed the whole organ, and to facilitate the work divided the lower jaw at the symphysis. The knife was used to divide the tongue near the hyoid bone, and few bolder deeds have been done in modern surgery. Others, particularly the late Mr. Nunneley, of Leeds, have removed the organ with wires, and some with the écresour, and patients have survived these formidable efforts to save them. With some the results seem to have been permanently successful, but I have doubts if in such cases the disease has really been malignant. Any how I must say for my personal experience, that as a rule most of the operations which I have performed on this organ, although at first highly satisfactory, have been unsuccessful in averting the fatal return of the malignant disease which called for the proceeding.

In April, 1867, I had under my charge in King's College Hospital a remarkable case of enlargement of the tongue. The patient was a girl of seven years of age. From birth the tongue had been much larger than natural. When five years old she had an attack of fever and sore throat, and after this the organ increased rapidly until it attained such a size as may be imagined from this figure (338), from a photograph taken before an operation was performed. The portion in front of the lips was about three inches long, two and a half broad, and nearly an inch and a half thick. I watched this case for some time, and came to the conclusion that the child would die from want of nourishment unless the mass was got rid of. I attempted by means of ligatures to cause strangulation of all the part in front of the teeth. One of the ligatures was accidentally cut after being drawn tight, and some free bleeding was arrested by ordinary ligatures to the vessels. The mass finally sloughed away, and a most satisfactory result ensued. The lips could be closed, but the teeth could not afterwards be approximated, as the jaws had been distorted by the long continuance of the pro-
trusion. I have known ligature of the lingual arteries tried in such a case, but with no good effect. In such an instance the admirers of the écraseur would revel. For my own part I should feel inclined, were I to meet another example, to make more free use of the knife and ordinary ligatures.

The uvula is sometimes so long that a portion of it should be removed. When from chronic elongation its point falls upon the epiglottis or upper orifice of the larynx, it excites troublesome cough and otherwise might do much harm; and, supposing that general treatment and astringent applications have proved of no avail, the operation for its removal may be done thus: The patient being seated in a good light, his head secured on the back of a chair or held on the breast of an assistant, the free end should be seized with long-beaked forceps, a sharp hook, or some such instrument, and then with a blunt-pointed bistoury, or with scissors, the apex should be removed. It is a good precaution to lay hold of the part previous to division, else it might drop into the larynx. I generally find that by standing on the patient's right side, and looking over his head, as it were, I can accomplish this proceeding better than in any other way.

The amygdala are often permanently enlarged: the condition gives rise to difficulty of swallowing, sometimes even of breathing; change of voice, hoarseness, deafness, and other ailments, and in the event of constitutional remedies and local applications having proved of no service, either as regards the state of the mucous membrane or tonsils, then a portion of one or both glands should be removed. The proceeding may be accomplished thus:—The patient, seated as in the former operation, should be desired to open the mouth as completely as possible, when the swollen part should be seized with a vulsellum such as represented in figure 339, or with hook-beaked forceps like that in figure 340, and with a curved probe-pointed bistoury (p. 88), the requisite incision should be made between the claws and the side of the pharynx. The opposite tonsil must then, if required, be treated in the same manner. It will rarely happen that the bleeding does not cease in the course of a short time, with the contact of the air and the use of cold water, or the application of powdered alum. I have known a solution of creosote answer when the latter had produced no benefit.

When the left side is the seat of operation, the surgeon, if he stands in front of the patient, can easily use the vulsellum in his left hand and the bistoury in the right, but if the opposite tonsil is affected, unless he possesses more ambidexterity than most men, he may not so readily hold the instruments in different hands: he will then find it most convenient to stand on the right side, as recommended for
removal of the uvula, when he can still hold the forceps or vulsellum in the left hand, and the bistoury in the right.

Mr. Liston preferred such an instrument as that represented in figure 339 for these operations; but a common sharp hook, single or double (p. 6), or a tenaculum, may be used. Generally I employ a forceps with claw-points, made longer than those referred to at p. 31. Numerous ingenious contrivances have been devised for the removal of portions of the tonsils, by Drs. Physick, Mitchell, Fahnestock, and others (most of which may be seen in the shops of the different instrument makers), but I give a decided preference to those above recommended. If scissors are selected, the blade should be rounded at the points, slightly curved, and sufficiently long to reach the throat with ease. When a bistoury is used, its heel should be wrapped round with a few turns of surgeon's lint, or this part may be purposely kept blunt, so that the lips may not be cut. Sometimes this instrument is carried through the swelling from above downwards, at others from below upwards, according to the taste or convenience of the operator. Supposing the operation required on the left side, the accompanying drawing (figure 340) will give a tolerably accurate idea of how the instruments should be placed. It is here presumed that the surgeon is standing in front of his patient, having the forceps in the left hand and the bistoury in the right.

In almost all the operations on the uvula and tonsils above referred to, I have for many years been in the habit of standing behind the patient, holding his head on my breast and looking over the upper part of his face into the mouth. For the uvula and right tonsil such a plan answers admirably, especially by those who prefer the cutting instrument in the right hand. The patient's head should be sufficiently low to let the surgeon see clearly into the mouth.

Scarifications are sometimes made in the palate or fauces in severe inflammation, but such manoeuvres require no special notice. Sometimes abscesses require to be opened here in examples of acute cyananche. For such a proceeding I use a lancet like that represented on p. 84, figure 70, or a long, narrow, sharp-pointed bistoury, with its heel and blade enveloped in lint to within half an inch of the
point, as this saves the necessity for having a lancet set in a sheath, which some have recommended for this purpose.

At all times in cases of deafness the condition of the mucous membrane of the pharynx merits attention, for when there is much chronic thickening in this situation, the Eustachian tube will probably not perform its functions with full effect. But besides attending to the throat in such cases, the external ear should be carefully examined. Here collections of wax, pellets of cotton which may have been unwittingly allowed to remain, insects, seed-pickle, pebbles, and such like, may obstruct the passage; chronic inflammation may cause thickening of the lining membrane: there may be granulations projecting from it in the form of polypi, or possibly acute inflammation and abscess may have ended in caries or necrosis of part of the neighbouring bones. The ordinary principles of surgery will serve to point out the routine of practice in most of these cases. Syringing frequently with tepid water will often be of great service, but sometimes it will be necessary to resort to the use of instruments to extract foreign substances, or remove excrescences. There may be some danger in attempting to separate diseased or dead bone here, and the surgeon should have a good idea of its limits before using any violence.

On one occasion I extracted, with the common dissecting forceps, a cap of brass, such as is put on the end of a pencil, which had been impacted for twenty-four hours; in another instance I removed with the scoop-end of a director a small flat-shaped pebble, which had pressed on the tympanum, and caused deafness for ten years; and I have frequently performed similar operations under various circumstances. Generally such cases occur in children, and with them as well as with the adult, chloroform may be used with great advantage. The instrument which I have found of greatest use on these occasions, Fig. 341.

is one made of iron plated, represented by figure 341, with a scoop at each end of different sizes, the large or small being used according to the supposed size of the object to be extracted.

It is often desirable to have a clear view into the external auditory passage, and various kinds of speculums have been devised for such examinations. The instrument in common use is a sort of tube about an inch and a quarter long, of a round or flat shape, of a size proportioned to that of the passage into which it is intended to be passed, having a clear polished surface internally. Some have preferred the surface blackened, and a common modification is to have the tube made of two lateral portions, which, by means of handles and a spring, can be made to open and shut at will. For ordinary purposes the handle of a common silver director (p. 12) will serve to straighten the passage sufficiently to permit the light to pass inwards, but for very careful
examinations some such speculum as those above referred to must be used. The late Dr. Warden of Edinburgh paid great attention to this subject, and devised a most beautiful and ingenious apparatus for throwing a strong light upon the tympanum by means of a glass prism and polished tube. A particular description of the instrument will be found in the Edinburgh Philosophical Journal for October, 1844, and Dr. Warden published in various British Journals of the day a variety of examples in which its application had been followed by most satisfactory results, having by its means been enabled to ascertain the condition of the tympanum in a more accurate manner than by other methods. The late Mr. Avery, of Charing Cross Hospital, also bestowed much pains in the construction of an auriscope, and was very successful in his object. In the apparatus which he devised a very strong light from a lamp is caused by means of a reflector to pass along a narrow tube introduced into the passage, and the surgeon’s eyes are at the same time so completely protected from unpleasant glare that he can make the most careful survey of the membrana tympani. With either of these two instruments I have seen minute objects at the end of a straight tube six or eight inches long, and not greater in diameter than a moderate sized catheter. Mr. Avery on one occasion showed me the blood-vessels in the living semi-transparent membrane at the bottom of the external auditory passage. In absence of such ingenious instruments and the sun’s rays being obscure, a strong light may be cast in the passage by means of a bull’s-eye lantern. Mr. Avery, than whom a more genial cultivator of surgical science never lived, has now been long dead, yet it has astonished me how within twenty years of that event men have claimed the invention for which he obtained from the Royal Society of Arts a medal of approval,—the self-same instrument which I have seen him use morc than twenty years ago.

The operation, proposed by Sir Astley Cooper, and at one time so highly prized, of puncturing the membrana tympani, is seldom resorted to, nor does there seem much encouragement to attempt the restoration of hearing by such a proceeding, simple and harmless though it be. The late Dr. Mercer, of Edinburgh, tried the operation more frequently than any other person that I know of, but the results were most unsatisfactory, for, out of fifteen cases which were punctured, some two, others three and four times, only one derived benefit; in the other fourteen there was, to use Dr. Mercer’s own words, “no effect.” This gentleman published a most interesting paper on the subject in the first volume of the Northern Journal of Medicine. He prefers an instrument of a simple kind, not unlike Scarpa’s needle for cataract (p. 479), but straight at the point and larger, to others of a more complicated character which have been recommended by different surgeons who have performed the operation. The point is passed against the membrane and drilled gradually through, so as to make a round opening sufficiently large that it may not close again; but should this happen, the proceeding is repeated.

The malformation of hare-lip, already referred to in preceding pages,
is frequently accompanied with fissure in the roof of the mouth, and the defect may be in a portion or the whole of the soft velum, or it may also involve the hard palate and alveoli. The fissure posteriorly is always in the middle, and anteriorly it appears to be there also, but the septum is generally attached to one side or other in such instances, for it is rare to see both nostrils communicating with the mouth in this locality. The cleft may involve only a portion of the osseous vault, or it may extend through the alveoli in front; and although in the latter shape it may be that the lip is entire, in the generality of instances this part is defective likewise. There may be a narrow cleft, or the gap may be such that mouth and nostrils seem as one.

Figure 342 represents the condition of the hard palate in an instance of fissure extending throughout the vault of the mouth. The straight line (a) is the lower surface of the vomer, which here runs as a single line to unite with the intermaxillary portions referred to at p. 497, on hare-lip. Here the vomer forms, as usual, a partition between the nostrils, but the palatine plates of the superior maxilla on each side are deficient, and leave one larger gap between them. That gap in front is divided into two, by the presence of the intermaxillary portions above referred to. The sketch represents the parts in a fetus about seven months old, and there was a double hare-lip conjoined with the cleft palate. Such preparations are rarely met with: one has been represented by Sandifort in his Observationes Anatomico-pathologicae, but I am not aware that the exact condition of the parts in this state has ever been represented before by any surgeon in this country. Judging from the specimen from which this drawing was taken, and others which have come under my notice, especially from numerous observations on the living body, I believe that the description above given will be found correct. This almost unique specimen, with others bearing on this subject and on hare-lip, is now in the museum of the Royal College of Surgeons of England, and to those who are specially interested in this subject, I may recommend my lectures at the College of Surgeons, delivered in 1864.

The length of fissure, both in the soft and osseous parts, varies to a great extent,—from the simple bifid uvula to the instance where the mouth and both nostrils seem almost as one huge space, having the turbinated bones and vomer projecting above. Sometimes a fissure, in conjunction with hare-lip, runs through the alveolus, implicating the front of the nostril without going further, but more generally the deficiency is towards the back part of the vault. In some rare instances there is an oval opening in the vault,
involving either the soft or hard palate, while all in front and behind is entire.

In all such cases the voice and articulation are more or less affected; in infancy little heed is taken of these defects, but at school age or afterwards there is much desire for amendment. Formerly an artificial palate, or obturator, made of gold, or other suitable material, was all that could be applied; but in modern times the cleft palate has been treated by Roux, Graefe, Warren, and others, in the manner of hare-lip, i.e. the margins having been pared and brought together by interrupted sutures, so as to produce union by the first intention;—thus closing the fissure, and making the palate as if no such malformation had ever been present. In the pamphlet which Roux published on this subject many years ago, a variety of instruments,—needles, *porte aiguille*, &c., are described—but most of them may, in my opinion, be dispensed with.

Staphyloraphy (as the operation is often termed) may be done thus: The patient should be seated in a good light, and his head should rest on the breast of an assistant: the surgeon should then seize the portion of the uvula on one side of the fissure, with long hook-beaked forceps (p. 31), draw it slightly forwards, and then carry a probe-pointed bistoury from the posterior border of the velum to the anterior part of the fissure in the soft palate, so as to make a clean-cut raw surface on its margin; then the other side should be treated in the same way, or by seizing the margin about the middle of the cleft, it may be held firmly until the knife, which for this purpose should be sharp-pointed, as in figure 344, is pushed through and run backwards and forwards: next a needle, set in a handle (p. 35), armed with a thread of the ordinary size for the interrupted suture, should be passed from below upwards on one side of the cleft, about a quarter of an inch from the margin: the thread being seized with forceps, one end of it should be pulled forwards; the needle should now be withdrawn, threaded with another ligature, and then exactly opposite pushed from below upwards on the other side of the fissure, at the same distance from its cut surface, when the thread should again be extricated with forceps, and the needle at the same time withdrawn: one of the ends thus brought to the mesial line should then be attached to the other end, and by drawing either the one or the other through the opposite side, it will be found that a double thread, which can readily be made single by pulling out one of the ends, has been carried across the gap: two, three, or perhaps four, threads being introduced in the same manner, each should be tied in such a way as to keep the edges in close approximation, and the ends being cut off, the operation is accomplished.

Figure 343 shows by the dotted lines how
much should be taken from each margin of the cleft, and the three black spots on each side indicate the site of the stitches. Figure 344 represents the shape and size of the sharp-pointed blade above referred to, and I generally prefer it to the one with the blunt point, which some have thought more safe for use in this locality.

Fig. 344.

Various modifications of this proceeding may be deemed advisable; thus, the threads may be introduced before the incisions are made: the edges may be pared with scissors instead of a knife; a short curved needle, attached to each end of the thread, may be introduced from above downwards; but all these matters may be left to the discretion of the surgeon. I need scarcely say, that such an operation can be done only in the soft palate; but should the fissure extend further forward, as it often does, especially in instances of hare-lip, the aperture in front can be afterwards closed with an artificial palate. Unless the patient is remarkably steady and determined to permit the operation to be finished, it will be needless to attempt it; and as such fortitude is not to be expected before the age of puberty, it will seldom happen that the surgeon's services are required prior to this period. Even when he has finished the proceedings in a most satisfactory manner, he must not be over sanguine of a fortunate result. Every precaution must be taken to prevent movement of the palate; the patient should partake of a meal immediately before the operation, and for the first two days should swallow only a little liquid, which he should allow to pass into the pharynx with the smallest possible drag on the stitches; at other times he should not permit the saliva even to pass backwards. The stitches should be carefully cut out (p. 50) on the second or third day, and on no account whatever should he partake of solid food, until all risk of the wound tearing open has passed away.

When a person grows up with this malformation, he, from custom, feels but little the physical inabilities of the part: he usually can swallow well, although perhaps when a child some of his food and drink would occasionally have got into the nostrils. The first case in which Roux operated affords as good an example of the annoying nature of the defect, and the efficacy of the proceeding, as any that could be adduced. A young medical man, with a tone of voice similar to that of those who have lost the soft palate by disease, asked the Professor if anything could be done for him. Staphyloraphy was the result; and when the patient returned among his friends, he was so greatly improved that (in so far as his voice was concerned) he could scarcely be recognised as the same individual.

Since the above notice of staphyloraphy was penned my own views regarding the operation have been considerably changed, and, if I may so say, enlarged. Experience has taught me that, with the modifica-
tions of the operation afterwards referred to, the patients may have a liberal allowance of liquid nourishment; that wine may be given freely if thought needful, and medicine also; and in many of these cases I have for years been in the habit of leaving the stitches for six, eight, or ten days with seeming advantage. Having an opportunity of making an anatomical examination of the cleft palate, I was in consequence led to suppose that one principal cause of failure was probably the great mobility of the parts, from the peculiar muscular apparatus connected with each side of the soft velum, and imagined that under certain circumstances the palato-pharyngei and levatores palati muscles might induce dragging on the stitches, with separation again in the mesial line, and that possibly the palato-glossus on each side might have some effect of this kind also. I resolved, therefore, to divide these muscles on the first favourable opportunity, and being satisfied with the result, brought the subject under the notice of the Royal Medical and Chirurgical Society, in December, 1844, in a paper which was honoured with a place in the volume of the Transactions of that body for 1845. Various incisions in the soft parts were devised by Roux, Dieffenbach, Mettauer, Liston, and Warren, all, in my humble judgment, without reference to the anatomy of the parts; but the subject is discussed at greater length in the paper alluded to than is in accordance with the arrangements of this work, and I must therefore refer those who are interested to that essay, and to various writings and lectures of mine on the subject, published in the medical journals, particularly the Medical Times and London Monthly, since the date of my first paper.

Fig. 345.

Fig. 346.

The operation which I now perform is similar to that already described, but with the addition of the muscular divisions, which are effected thus:—Previous to paring the edges of cleft, a knife such as one or other of the two represented in figures 345 and 346 is passed through the fissure, so that its points can be laid on the tissues immediately above the soft velum, midway between its attachment to the bones and the posterior margin, and about half-way between the velum and the lower end of the Eustachian tube; the point is then thrust deep, and carried half an inch or more backwards and forwards, so
as to cut the levator palati across in a line indicated by letter \( a \) in drawing 348: next, the uvula is seized with a pair of long hook-beaked forceps (p. 31), and drawn forwards, so as to put the posterior pillar of the fæces on the stretch, which is then snipped across with long curved scissors (figure 347) about half an inch behind the tonsil in the line marked \( b \) in the drawing referred to (348), by which cut the principal part of the palato-pharyngeus will be divided; then, if it seems desirable, the anterior pillar of the fæces is touched with the scissors so as to make the section of the palato-glossus,—a proceeding which I scarcely deem requisite. These steps being accomplished on each side, the rest of the operation may be conducted as described above. In some instances it seems difficult to arrest any muscular movement by these incisions, and I am inclined to attribute this to the action of that end of the palato-pharyngeus which is attached in front to the palate bone, as also to vermicular motion in the muscles after division; but, even though this be the case, the soft flap on each side is much more under the surgeon's command than if no such preliminary wounds be made; the needles can be more readily introduced, and the margins of the gap can be brought together with greater facility, while there is infinitely less drag upon the stitches when they are knotted. In the operation without these incisions there is trouble in keeping the first noose of the ligature tight until the next is cast. This is less likely to happen if the course I advise be pursued.

* The cut represents the posterior nares and upper surface of the soft palate. \( a \). The levator palati; the dark line shows where it should be cut across. \( b \). The inner bundle of fibres of the palato-pharyngeus forming the posterior pillar of the fæces; the black line indicates the place for division. \( c \). The palato-glossus, with the mark for incision, if one should be deemed necessary. The tonsil lies between these two muscles. \( d \). The tensor palati, the cartilaginous extremity of the Eustachian tube is in front of this letter. \( e \). The posterior extremity of the inferior turbinate bone. \( f \). The septum. \( g, g \). The uvula on each side stretched apart.
The surgeon's knot (p. 29) may be used, or that represented in figure 349, which I now almost invariably prefer to any other. This noose and knot are made thus: a loop on one side is drawn tight upon the other, and run up so as to insure the approximation of the edges, when a common knot must afterwards be tied on the two ends. There is less risk of slipping by this plan than even by the surgeon's noose, and the whole, while perfectly secure, will have less bulk in the roof of the mouth than the smallest bead suture, such as has been recommended by Mr. Brooke and others for this operation.

If care be taken in dividing the levator palati not to run the knife towards the upper and back part of the pharynx, there is no harm to be dreaded from the incision above described. Were the instrument carried far upwards and backwards, the internal carotid would be in danger; but if its point be pushed straight outwards and forwards, it will sink into the pterygoid fossa, and possibly divide the tensor palati muscle, when it can come in contact with the external pterygoid process only. In my original paper I have expressed an opinion that the division of the tensor palati does not seem to be required, as that muscle has a very feeble influence over the movements of the velum, and latterly I have almost ceased to divide the palato-pharyngei excepting in the widest gaps.

I have now operated above two hundred times according to the method last described, and have been successful in all of them but some five or six. One of the cases of failure was most unfavourable for an operation, in consequence of the narrowness of the lateral portions; but the want of success was probably, after all, more attributable to deficiency of skill on my part in dealing with the stitches, than from any imperfection in the proceedings otherwise: in my anxiety to have complete closure, I used more stitches than were absolutely required, and, above all, pulled them too tight,—for the sloughing which took place in the mesial line exactly in the part included between the lateral boundaries of the threads, was, I imagine, the result of these two circumstances. A second unsuccessful case was on a youth of ten years old, who, notwithstanding my advice to wait until the mouth should be more developed, most earnestly entreated that the operation should be done. Two stitches were introduced, but the parts opened on the third day. In the third instance, the cut surfaces took an unhealthy action, and the gap opened again. I thought at the time that I erred in removing the stitches too early, and have since closed this palate satisfactorily, by a repetition of the operation. I believe, however, that an absence of healthy action has been in reality
the chief cause of failure. The soft tissues usually swell so much after this operation that it is unwise to draw the threads tight; for if this be done, ulceration at least (if not sloughing) will ensue, an action which Mr. Bushe, of New York, seemed to imagine invariably occurs in the site of the stitches, for he remarked that in the operations which he performed, the part of the wound immediately under each thread was the only point which did not unite by the first intention—an observation which I have myself had occasion to make in several instances where the stitches seemed rather tight.

In some of the successful operations above referred to, the ordinary proceeding had been previously done, but had failed. Mr. Bowman succeeded in this way by a second operation, and I saw a case with Mr. Tatum, of St. George's, where there were similar results. Among various surgeons who have given this operation a trial after the manner which I have recommended, I may particularly name the late Mr. Avery, Mr. Quain, Mr. Gay, Mr. Walton, and Mr. Thomas Smith, of St. Bartholomew's, who has added important materials to the development of this subject. The last-named gentleman has recommended an instrument of special construction for keeping the mouth open during the performance of the operation, and has also been more zealous in the use of chloroform than any other I know of. I have used chloroform again and again, but have had so little satisfaction with it that I strongly recommend the operation without it. This is in fact almost the only operation in surgery in which I dissuade from the use of this agent. It has been used with what some call success—and I have so used it myself—but a dangerous risk to life.

The above operation, as already stated, has reference to the soft parts only; and until a very recent date no attempt has been made by the surgeon to close the gap in the palate, excepting by means of an obturator, which has always been supplied by the dentist. The late Mr. A. Nasmyth presented in 1845 to the Medical and Chirurgical Society a most interesting paper on the subject of obturators and artificial palates, wherein he showed that with all their utility they were nevertheless far from being faultless. Dr. J. Mason Warren, of Boston, however, closed the fissure here, as well as in the soft parts, by a proceeding strictly surgical: he dissected the soft tissues from the hard vault of the mouth, between the margin of the cleft and the alveoli, and then closed them in the mesial line by a proceeding analogous to the operation in the soft palate, and reported (in the New England Quarterly Journal of Medicine and Surgery, for April, 1843) most favourably of the result. I have resorted to the operation in many instances, but with partial success; yet the plan seems so clever and reasonable that I recommend it for further trial. The process is exceedingly difficult, and will, in my opinion, be accomplished most readily by means of blades similar to those represented in figures 345 and 346. The late Mr. Avery paid much attention to this latter part of the subject, and more recently it has again been prominently noticed by Mr. Pollock, of St. George's Hospital, from whose pen an excellent paper has been published relating to it, in the volume of the Transae-
tions of the Medico-Chirurgical Society for 1856. Mr. Field, of Brighton, has also drawn particular attention to the subject.

Since the last edition of this work, special attention has been drawn to this subject in consequence of certain persons having claimed to have inaugurated this practice of peeling down the soft from the hard palate. The merit is due originally, I believe, to the late Dr. Mason Warren, whilst some modifications in effecting the process have been introduced by others. Thus, instead of beginning at the margin of the fissure, it has been proposed to make an incision parallel with the alveoli through the soft tissue covering the hard palate, and to carry the knife towards the free margin of the fissure. This I think an excellent plan, as the soft tissue is thereby further relaxed. I have found it answer admirably. Langenbeck aims in such a process at tearing the periosteum from the bone, under the impression that new bone may be developed upon it, and so fill up the gap where the bone is originally deficient. I have myself no confidence in this theory, as I call it, but I am of opinion that when union does occur in the mesial line, the side plates of bone are occasionally so drawn towards the centre that there seems complete ossification.

As regards the voice after such an operation, in some instances there has scarcely been an appreciable improvement, but in others, and, I am glad to say the majority, the effect has been most gratifying. In some the change in tone has been perceptible at once, while in others many months have elapsed ere much could be noticed. In all instances where there has ultimately been great improvement, correct modulation of tone has been acquired only after the lapse of considerable time.

Sometimes holes are found in the roof of the mouth as the result of disease, and various attempts have been made to close them. In the soft palate the caustic, or cautery, has sometimes sufficed; but in the hard parts these means have usually failed. The surgeon has sometimes succeeded by a plastic operation in filling up such gaps, and I can suppose that in some such instances the process of Dr. J. M. Warren might be of service. In several examples I have tried this plan, but without success, and in the generality of such cases I believe that the patient had best remain satisfied with an obturator. Instead of gold or other metallic plate, a bit of bone or ivory, caoutchouc, or even dough, will suffice in such instances. Mr. C. H. Stearns, of America, discovered a preparation of caoutchouc which seemed peculiarly applicable for such purposes, and devised the most ingenious apparatus for the cleft palate which I have ever yet seen. Mr. S. had the kindness to show me this piece of mechanism; and a more detailed account of it will be found in The Lancet, 5th July, 1845, to which Journal for September of the same year I may refer for additional observations by that gentleman. It does not appear that this apparatus has been extensively applied in these cases, doubtless from the perishable nature of the material, yet within these few years this method, with certain modifications, has been revived, although, as I have reason to think, with no permanent good results.
The lower jaw occasionally becomes so closely bound to the upper, that the teeth cannot be sufficiently separated to admit of solid food. This condition may arise from inflammation and adhesion of the gums, especially after necrosis of the alveolar processes: sometimes it is the result of chronic contraction of a muscle; occasionally it has been accompanied with ankylosis, of which there is a remarkable specimen in the possession of M. Dubreuil of Montpelier; and in certain examples it is difficult to say what is the cause. Some years ago I had a patient with the mouth thus contracted, and in whom there was a portion of the lower jaw in a state of caries: the disease was not in a condition that I could, with propriety, attempt its entire removal. A portion of bone, however, was excised, but little benefit resulted, and what there was might probably be attributed more to the use of a screw-dilator, than to the partial removal of what I considered a source of irritation. Mott succeeded in two instances in relieving such permanent adstrictions; and in the first volume of The Provincial Medical and Surgical Journal, there is a case recorded wherein I was fortunate enough to produce a similar effect by dividing the masseter on one side with a narrow knife, passed from the mouth between that muscle and the skin. If ankylosis be the cause of closure, it is doubtful if the surgeon would be justified in interfering. In certain cases there seems reason to suppose that the rigidity, from whatever cause it may be, is only on one side, and it has been proposed to cut the bone perpendicularly so as to set free the healthy side. This has been done with seeming benefit in some cases, and to prevent union by bone again, as has happened, even a bit of the jaw has been cut away. This subject has been ably handled by Mr. Heath, in his Jacksonian Essay on the Surgery of the Jaws, for which the prize was awarded in 1867. In the course of my experience I have seen many instances of the kind above referred to, but feel bound to state that most of my attempts at improvement have utterly failed.

CHAPTER VII.

VARIOUS OPERATIONS.

LIGATURE OF ARTERIES.

On the back of the neck few operations of great consequence are ever required. The application of the cupping apparatus, or the introduction of a seton, are, perhaps, the chief of them, and no particular notice of either is here necessary. The skin in this situation is so thick, that the lancets may be allowed to penetrate to any reasonable depth, as there will be no danger of coming in contact with important organs: it is not, however, considered advantageous to
make very deep wounds in the operation of cupping. The seton is used more frequently in this region than in any other part of the body. The cord is generally introduced three or four inches below the occipital protuberance, being carried in a transverse direction about an inch in length under the skin. The most convenient mode of passing it is such as has already been described at p. 64. Occasionally it is necessary to remove tumours from this part; and as these are usually superficial, there is little care or skill required in such operations. Some time since I removed a fibrous growth about the size of a fist, which had been present for many years, and prevented the development of the upper ends of the large muscles in this situation: the mass was in contact with the occipital bone, touched the upper cervical vertebra, and considerable caution was required for its separation. The occipital artery and some of its branches bled freely. The patient had so long carried his head in a stooping position, that little benefit in this respect was derived from the operation; otherwise, however, he had got rid of a considerable deformity, and had more facility in moving his head. Carbuncles are perhaps more frequent in this locality than in any other, and when incisions are deemed requisite, the knife may be used freely and deeply, as no important part is in the way.

On the side of the neck venesection is occasionally performed in the external jugular. That part of the vessel over the sterno-mastoid muscle is the seat of operation, and here, as the vein lies under the platysma myoides, it may be well to keep in mind the recommendation to carry the lancet across the fibres of this muscle, as there will thus be less chance of a thrombus forming under it. In other words, the incision may be made parallel with the sterno-mastoid. Perhaps the best reason for this proceeding is, that the vein will be cut obliquely; for, though I do not mean to deny that the fibres of the platysma, if not divided, may obstruct the flow of blood, I believe that more importance has been attached to this circumstance than it really deserves, having often seen the blood flow freely with the wound made in either direction. Probably the varied size of the vein in different individuals will sufficiently account for the stream flowing more readily in one than another. Nevertheless, as it is as easy to make an incision in one direction as the other, it will be best to divide the platysma over the vein, and thus obviate any obstruction which these fibres, if left uncut, might offer to the flow of blood. The lancet must be held and used in the manner already described in other pages, and care must be taken that the orifice in the skin is fairly over that in the vein, and that it is kept steadily in this position until the desired quantity of blood is drawn. To retard the circulation in the lower part of the vessel a pad may be placed at the root of the neck, over the vein, and retained by a bandage carried under the armpit of the opposite side; but this will seldom be necessary, as a little pressure with the thumb or forefinger of the left hand will keep the vein sufficiently distended during all the desired period. When the pressure is taken off the stream will cease, and the wound, being
covered with a piece of lint or slip of plaster, will heal like that in
venesection at the elbow.

Ligature of the main arteries may next claim attention. The sub-
clavian, as has already been stated in a chapter on the Upper Extremity,
is now usually secured above the clavicle, when it is necessary to
interfere with the vessel at a distance from injury or disease. Under
ordinary circumstances the seat of deligation is immediately on the
outer (acromial) margin of the scalenus anticus muscle, and here the
operation may be done on the subject in the following manner:—The
body being placed on its back, with the chest raised on a block, and
the head also elevated, and slightly turned to the opposite side,
the shoulder, on that side on which the proceedings are to be accom-
plished, is to be drawn downwards and forwards, when (the operator
standing on whichever side is most convenient) an incision should be
made between three and four
inches long, and about half
an inch above and parallel with
the clavicle, one end being
over the clavicular portion of
the sterno-mastoid, the other
over the anterior margin of
the trapezius. This incision
(letter b, figure 350) will be
slightly lunated, and should
expose the fibres of the pla-
tysma myoides, and probably
two or three cutaneous nerves
running in the same course.
The knife should again be ap-
plied to divide this muscle and
any texture over it which may
not have already been cut,
when the margins of the sterno-
mastoid and the trapezius will in all probability be exposed; pos-
sibly, however, the trapezius may not be seen, and, indeed, unless
it is apparent that this muscle has a more than usually extensive
attachment to the clavicle, there is no particular occasion for carrying
the first incision so far outwards. The external jugular vein will
now perhaps be exposed, when it should be slightly loosened, and held
by a blunt hook towards the trachea or acromion, according to its
proximity to these parts: generally it will be most convenient to
draw it inwards; but should it appear in the way, a couple of liga-
tures may be applied, and the vessel divided between them. Now the
dissection should be cautiously continued through the fat and cel-
lar substance, when the posterior belly of the omohyoid muscle
will be brought into view: a blunt hook should be used to draw it
gently upwards, and then the space between it and the clavicle will be
increased. Here the knife should be applied very cautiously, and
not before the parts have been examined with the eye and point of
the finger; the handle of the instrument, or a silver blade, may be called into requisition; for, besides the danger of coming in contact with the artery or vein, there is the risk of wounding some of their branches.

If, after a careful division of the textures supposed to lie over the artery, the vessel is not yet exposed, the anterior scalenus muscle should be looked for, and to facilitate this step a few of the fibres of the sterno-mastoid may, if required, be divided,—indeed, whenever this muscle takes a broad attachment to the clavicle, there should be no hesitation about this proceeding, and thus the scalenmus will be readily exposed by separating with the handle of the knife the cellular tissue immediately over it. The forefinger should now be run down to the attachment of this muscle to the first rib, and immediately outside and a little behind this point the artery may be felt pulsating; a slight and cautious dissection will now expose a small portion of the vessel: when its identity has been ascertained, the point of the aneurismal needle should be carried under it, from before backwards, and thus the ligature may be conveyed around it. On the living body, when the needle is under the artery, or before the noose is drawn, the vessel may be slightly elevated and compressed with the point of the finger, and by watching the effects of this manoeuvre on the pulse at the wrist and on the aneurismal tumour—if one be present, all further doubts (if any still remain) about the vessel will be set at rest. The ligature may now be tightened; one or both ends should be allowed to hang out of the wound, the edges of which, on the living body, may be kept in apposition with a couple of stitches, and treated according to rules laid down in other parts of this volume.

On the dead subject the operation, as just described, may be readily accomplished;—few of the difficulties which have occasionally been encountered on the living will be met with. Sometimes, when the neck is short and muscular, the clavicle high, and the veins are turgid, there may be trouble, but not such as can be compared with that which may occur in practice. When the shoulder is elevated, the artery is nearly covered by the clavicle, and as a large aneurismal tumour in the axilla will have a similar effect by raising the bone, the difficulty in reaching the vessel, under such circumstances, may be thus in some measure appreciated, for when such a tumour is present the shoulder cannot be held down as when the parts are in a more natural condition. In an operation of this kind occurring in my own practice, the ligature within the wound was two inches and a quarter long, and yet the tumour in the axilla was not by any means so large as others which have been seen in this situation.

On the living body, the hemorrhage, especially if there is disease in the axilla, may be very troublesome, particularly from small veins which may not attract much notice in the healthy state of the parts. In such cases, if pressure cannot be applied with effect, I should not hesitate to apply ligatures to all the bleeding points: and here, as also with the external jugular, if this vessel should be tied as above re-
commended, I should be inclined to allow the ligatures to remain; for in all the operations on the large arteries at the root of the neck which I have witnessed, where temporary ligatures have been used, I have invariably noticed that, after the patient has been put to bed, bleeding has occurred generally from the upper end of the vessels. Sometimes a vein may be so deep that a noose cannot be cast around it; or if, unfortunately, the subclavian itself should be wounded, then pressure after the operation can alone be depended upon. The main vein, however, is generally so far in front of and below the artery that, with ordinary precaution, there will be little difficulty in avoiding it. The supra-scapular and transversalis colli arteries are both in danger, and it is not easy to say which may be most so: the former is usually protected in some degree by the clavicle, and the latter is perhaps the most in the way, but is irregular in size and position,—and as both may be so, it will be well to have a sharp eye on the textures about to be cut. Were either of these vessels divided, or any other artery of considerable size, a ligature would be necessary.

Both touch and sight may be of the utmost service here, but they are not always so available as the dissector may imagine. Sometimes the pulsations of the main artery cannot be felt with the point of the forefinger, as once happened to myself when the tunics were thickened; and on other occasions they may be so feeble as to cause some doubt, as happened to Professor Todd, of Dublin. The depth of the wound may prevent a fair view of the parts, and for these reasons, then, when the needle is passed under the artery, it will be advisable to try the effects of compression, as above referred to, especially when it is remembered that on the living body a nerve has been mistaken for the vessel, and actually surrounded by the thread. In the instance alluded to the error was discovered immediately, and rectified at once. The large nerves are generally so placed behind and above the artery that they are certainly not much in the way, yet it is well to bear the above fact in mind. In recommending the artery to be "slightly elevated" with the needle or the thread, as has been done in the preceding page, I hope it will be understood that this gives no sanction to unnecessary rudeness, for the less the surgeon moves the vessel in this way, the more will he comply with the rules of good surgery.

It has been stated that the point of the needle should be introduced from before backwards, but some good authorities have recommended the opposite course. The former has been thought best for avoiding the vein; the latter has been found convenient in instances where the elevation of the clavicle has prevented the necessary depression of the handle of the needle. For my own part, I should follow whichever course I found least troublesome, taking care, however, to keep the point as close upon the artery as possible. When Mr. Ramsden first performed the operation, this was found to be the most difficult part of the whole proceeding. After using various forms of needles, the thread was at last carried under the artery by means of a common silver probe, bent at one end. Many ingenious contrivances have since been recommended (such as Weiss's, Mott's, Gibson's,
L'Estrange's, &c.), but I doubt if any one of them be superior to a needle such as represented at p. 34. In all it is absolutely necessary that the point should be carried under the vessel, so that it may be drawn or pushed up on the side opposite to that where the shank is placed, for this latter part, with the handle, cannot be depressed, as in the operations on most other arteries, so as to cause the point to rise high above the level of the vessel. I imagine, however, that if the point can be seen under and at one side of the vessel, there can be no further difficulty; for if the eye is close to the extremity (as it should be), as soon as it appears the thread may be seized with a hook or forceps, and drawn up, without the necessity for any depression of the handle whatever.

It is certain that in many (I should say in most) instances the common needle has been found to answer perfectly, but it is equally so that most expert operators have had great trouble in this part of the proceeding; and although I myself should first make use of such an instrument, I would assuredly be provided with various sorts in case of any difficulty. In 1831, I successfully applied a ligature to this vessel, with a needle of this shape \[\text{[diagram]}\] , the concavity near the handle being for the purpose of allowing the instrument to revolve, in a manner, over the clavicle. In that instance, however, I believe that a needle of the ordinary shape would have answered equally well. The case was published in the 109th number of The Edinburgh Medical and Surgical Journal, and was chiefly remarkable perhaps as having been the third successful operation of the kind which had at that date been performed in Scotland. Some further particulars were given in the September number (1841) of The London and Edinburgh Monthly Journal of Medical Science, including an account of the post-mortem appearances about four years after the operation.

In a deep wound there may be difficulty in drawing the noose and knot sufficiently tight with the fingers alone; for here, as in other parts, their points should, if possible, be kept close to the artery, so as not to raise it from its natural position, as would happen if this manoeuvre were not attended to. In deep and narrow wounds, then, some substitute for the fingers may perhaps be of service:—such as an instrument somewhat similar to the polypus forceps, represented in p. 490, having a small eye at the point of each blade, through which the ends of the ligature can be passed after the first noose has been cast. If these be closed, slid on the thread down to the artery, and then opened, whilst each end of the ligature is held firmly, the noose can thus be tightened, and then the second may be drawn in a similar manner. Two rods of iron, about the diameter of a quill, each having a small aperture at one end, have been used in a like manner,—they are long, narrow substitutes, as it were, for the fingers; but the latter should always be preferred, where they can be applied, and I believe that, if dexterously used, they will seldom be found incapable of
fulfilling the wishes of the surgeon. In whatever way the knot is drawn tight, it is advisable, after the first twist is effected, to apply a little pressure with the point of the finger until the second is completed. An assistant generally does this; and when the finger cannot be conveniently used, the common forceps (p. 5) may be applied with advantage. Possibly such a contrivance as that which I follow in tying the stitches in cleft palate may be of service on some of these occasions.

An additional turn of the thread is a wise precaution, as it is just possible that those already made may actually become loose, and in this situation I prefer allowing both ends of the ligature to hang from the wound; but on this subject I must refer to the third chapter of the introductory section of this work.

In looking over the history of axillary aneurisms, for which ligature of the subclavian has been performed, one cannot but be struck with the frequency of suppuration occurring afterwards in the tumour. My attention was first directed to the circumstance by a case under my own care, when I found that it had happened in Mr. Bullen's practice, and also with many others. Although this process appears to have been more frequent in this situation than in similar diseases elsewhere, it does not in general seem to be attended ultimately with bad results. In Mr. Bullen's case the abscess burst into the bronchial tubes, and also opened externally (air passing freely between the two), yet the patient did well. The course of practice to be pursued may be difficult to decide, for a feeling must always be uppermost that in opening the abscess the aneurismal sac must be wounded at the same time, and that possibly uncontrollable hemorrhage may ensue,—indeed I have known this happen in popliteal aneurism after ligature of the superficial femoral; but in general, if inflammation, fluctuation, and other symptoms be distinct, there should be no hesitation in making an opening at the prominence formed by the matter. This, however, should not be so very free as if the abscess were one of an ordinary kind, although the after-treatment should in most respects be the same. The cause of inflammation and suppuration in these cases has never yet been satisfactorily accounted for.

It has been the custom with some to speak of applying a ligature to the artery where it lies between the scaleni muscles, as a distinct operation, and the high authority of Dupuytren has been quoted on the subject. I confess, however, with all due deference to that distinguished name, that I have never been able to look upon it as a different operation. If from the size of an aneurism, or any other reason, the surgeon perceived that it would be improper to carry the external end of his incision so near to the trapezius as has been above recommended, he would (still supposing he could expose the vessel as it lies on the first rib) run the internal end nearer the trachea, and if on getting upon the artery, he found it diseased, he should certainly divide the anterior scalenus to ascertain the condition of the vessel behind it, and, in the event of its being healthy, apply a ligature, as he might do at the outer margin of the muscle in any other ease. In 1819,
Dupuytren operated on the left side, having the intention from the first of dividing this muscle, which he accordingly did, and the proceeding was successful. This case was an axillary aneurism, resulting from a stab. In 1820 Mr. Liston tied the vessel (with success) above the clavicle for a spontaneous aneurism, and in the progress of the operation found it necessary to divide a portion of the outer margin of the muscle. His original object was to secure the vessel after it had passed that point, but finding the tunics diseased, he, without making any alteration in the external wound, proceeded to treat the muscle in the manner alluded to.

Should it be deemed necessary to interfere with the scalenus, it must be remembered that the knife comes nearer and nearer to important parts. First, the posterior and supra-scapular arteries lie closer here to each other than farther on; then the phrenic nerve may be endangered, and even the internal jugular vein. The division of the fibres should be effected with a probe-pointed bistoury, and, as an additional security, a director should be pushed under the muscle. If any of the vessels above-named were visible, they should be held aside with hooks, or with a curved spatula, and the movements of the knife should be made with the utmost caution, especially if it were found necessary to divide the whole of the muscle, so that the phrenic nerve might not be injured. This nerve generally lies close upon the inner margin of the scalenus; but it may be a little towards the middle of its anterior surface, although it is perhaps more frequently separated from the margin by some loose cellular tissue.

In the dissecting-room it is an easy matter so to contrive the incisions as to permit a saw to be applied to the middle of the clavicle for the purpose of dividing it, and thus exposing the artery more completely. On the living subject, however, I can scarcely imagine such a case as to require or warrant this proceeding. If the aneurism is high, large, and encroaches on the clavicle, in all probability the bone will actually form a portion of the sac: here, then, such a step is inadmissible, and if the tumour is not in the condition described, I cannot suppose that the proceeding is at all necessary.

Perhaps in such a case as that just referred to, or in an instance of a small aneurism connected with the vessel between or immediately outside of the scaleni, the surgeon might endeavour to deligate the subclavian at a point still nearer the heart. Such an operation, however, can only be resorted to on the right side, for on the left the vessel lies so very deep that, in so far as I am aware, no such proceeding has ever been accomplished on the living body.

For ligature of the subclavian on the tracheal side of the scaleni muscles, the patient should be on his back, with the shoulders slightly raised, a pillow being placed under the neck, so as to allow his head to hang a little; care, however, being taken not to depress it so as to cause him much uneasiness. The surgeon should stand on the patient's right side, or at his head, being guided by circumstances or taste in selecting his place. For my own part I should prefer
standing at the end of the table, so as to look, as it were, over the patient's face.

Letter c on figure 351 points out the lines of incision for the external wound. It should commence nearly over the inner margin of the left sterno-mastoid muscle, and extend outwards in a slightly lunated direction, about three-fourths of an inch above the clavicle, for three inches or more. The skin, platysma myoides, and fascia, should be divided as in the operation last described: then the external portion of the right mastoid should be cut, after having passed a director or the point of the finger under it: next the sterno-hyoid and sterno-thyroid should be divided in the same cautious manner, and then the vessel should be looked for in the loose cellular tissue in this situation. The point of the knife should be used as little as possible, and its handle will probably be found sufficient for the greater part of this stage of the business. It may happen, as I have twice seen on the living subject, that the carotid artery comes first in view, and care must therefore be taken that no mistake occurs. This is not by any means probable; but as soon as the one vessel is recognised the operator will know that the other is not far distant. The carotid (supposing it to be thus first exposed) may be followed down to the innominata, and then the subclavian may be traced from this last-named vessel. In thus pursuing the course of the carotid, the cellular tissue should be separated only to such an extent as to permit the recognition of the vessel. It will be better, however, if this vessel can be left alone; and, therefore, whether it is seen or not the surgeon should keep close to that part of the wound immediately behind and above the end of the clavicle: by careful separation of the cellular membrane, he must come upon the artery, at a distance from the innominata of three-fourths of an inch perhaps, when the needle and thread should be passed from below upwards, with the same caution as has already been recommended for the operation on the acromial side of the scaleni.

If the circumstances are favourable, and the operator is an expert anatomist, the ligature may be applied without any important part, excepting the vessel, having been observed. Possibly, however, besides the glimpse of the carotid already alluded to, he may perceive the par vagum, some branches of the sympathetic, the internal jugular,
perhaps the vena innominata, and even the upper surface of the pleura. Some of the twigs of the sympathetic must of necessity, I imagine, be cut, and the par vagum can scarcely be avoided:—indeed, if that nerve is perceived, it will be a good guide to the artery, for by tracing it down the latter is certain to be reached. If this course is followed, however, the nerve should be fingered and touched with instruments as little as possible, for there is good reason to suppose that (physically or functionally) it may be seriously affected by such injuries. On all occasions it will be necessary to avoid including this nerve or the recurrent in the ligature, and only by great caution can such a serious evil be prevented. The internal jugular is certainly less in the way than the par vagum,—it will be on the outer side of the ligature, but yet so near that too much caution cannot be taken to protect it. The vena innominata is still less in the way than the other, as it lies rather under the level of the artery; but there may be smaller veins which will cause considerable annoyance if divided. These should be held aside with blunt hooks; if this be inconvenient, they may be tied and treated in the manner already recommended in the description of the operation on the outer side of the scaleni. The proximity of the pleura should not be overlooked: usually the connexion between it and the artery is very loose, and I do not suppose that the operator will be able to recognise it on all occasions: much care, however, must be taken in passing the needle, and perhaps the safest plan is to keep its point in close contact with the vessel. There is every reason to suppose that Mr. Colles (who was the first who tied the artery on the living subject in this situation) punctured the upper part of the membrane, and though it is certain that this had but little, if any, influence in the result of the operation, the surgeon should do all in his power to avoid it.

The ligature, when placed as directed, will be very close upon the vertebral artery, but this cannot be otherwise. This vessel, often irregular in its origin, may be on the distal or proximal side of the thread, although it will most probably be on the former. I cannot, however, recommend that the ligature should be placed nearer the heart, nor is it advisable to place it further from it. In the one instance the current of blood through the innominata and carotid might impede, prevent, or destroy the adhesion of the vessel at the seat of ligature, and in the other the recurrent circulation through the branches of the subclavian beyond the ligature might have a similar influence. The same remarks, it will be perceived, may be applied to the vertebral; but here the disadvantage cannot be avoided.

Were I asked to state which I thought the most difficult operation in surgery, I should at once name the one last described. A good knowledge of anatomy, great tact in discriminating textures, steadiness, coolness, and a ready use of the fingers and instruments, are all required in such a proceeding: the slightest carelessness with the knife,—a trifling deviation on one side or other,—may produce the most serious consequences, and no one should attempt it unless he feels assured that he possesses most or all of the above qualities.
Ligature of Arteries. Subclavian.

I have recommended that the sternal end of the sterno-mastoid should be cut, for I believe that the operation will be most readily accomplished by doing so. On the living body I should not hesitate to separate even the clavicular attachment also, and certainly should prefer doing so instead of only dividing the latter portion, as has been recommended by some. If the outer margin only of the muscle were divided, the surgeon would be certain to come right down upon the internal jugular vein;—the branches of the artery would be in his way, and possibly, too, the phrenic nerve would be in danger. On the dead subject the vessel can be readily secured by only interfering with the outer head of this muscle, and in such a case the sterno-hyoid and thyroid muscles need not be meddled with; but in every respect I should deem the operation more hazardous, and being attended with no advantage, that I am aware of, I should certainly prefer cutting for the artery in the manner first described.

In some subjects the two portions of the sterno-mastoid have a considerable space or slit between them, and in the dissecting-room the ligature of the vessel has been exhibited, by cutting between the two, holding them aside, and leaving the fibres untouched. Such a process and on such an occasion is usually simple enough; but I should be amazed at any one seriously attempting it on the living body. The idea that it is meritorious to save the fibres of this muscle uninjured, in an operation undertaken for an otherwise hopeless disease,—a proceeding, too, involving, it may be said, the immediate safety of the patient,—seems a refinement and nicety in operative surgery, which I cannot at all appreciate. The division of one half or even the whole of this muscle will not, in my opinion, make the smallest appreciable difference as to the ultimate success of the attempt thus made to save the patient's life, whilst it will greatly expedite the proceedings; and large though the gap may be, there will be more safety for the patient at the time, and less pain too, I imagine, than if the surgeon were to limit himself to so narrow a wound as there must be by following such a course as that which has induced me to make these remarks.

A single incision parallel with the clavicle has been recommended; but I would not limit myself if I found the wound deep and narrow, and the operation difficult. Such an additional cut as that marked d in figure 351, might be made with great advantage, or the knife might be carried so as to make the wound like an inverted \( \uparrow \) or a crucial \( \downarrow \) incision; but there need be no restriction as to the shape or size of the external wound, provided it is sufficiently free, and allows the parts beneath to be reached with facility.

As already stated, this operation was first done by Mr. Colles, of Dublin, in 1811, and since then it has been repeated several times. Hitherto, however, it has invariably been unsuccessful. In the spring of 1841, I assisted my colleague, Mr. Partridge, in its performance on
a patient in King's College Hospital. It is not possible to imagine such a proceeding to be better done, or with less injury to the surrounding parts. Everything seemed favourable; the tumour small and between the scaleni: the patient, a middle-aged, healthy, strong man, possessing great firmness and courage;—yet he died on the fourth day. The particulars of the case are given shortly in The Lancet for 1841.

Taking into consideration the want of success attending this operation, it may well be deemed a serious question whether it should again be attempted. For my own part, I should do it with great reluctance. Brasdor's operation has been talked of here, and a surgeon could not be blamed for performing it; but we have little to hope for from such a proceeding either; and under the circumstances I believe that one might be fully justified in amputating at the shoulder-joint, treating the stump in the ordinary manner, and keeping up steady and properly regulated pressure on the disease. This seems a shocking alternative,—nay, it is so; but it must be remembered that death is almost the certain result in any other way; and if there was a chance of life being preserved by such a sacrifice, it would be the duty of the surgeon to urge it. It is known that amputation at the shoulder-joint is generally a very successful operation; as far as this wound is concerned, then, there might be little to apprehend, but the effect on the tumour is not so easily foretold. Ligature of the axillary artery on the face of the stump might here be reckoned like Brasdor's operation,—yet there is a vast difference, for in the latter case the same amount of blood which previously passed towards the upper extremity would still find its way down, and probably part of it would run through the sac; whereas, were the member removed, as the same quantity would no longer be required in this direction, the tumour might possibly be much more under the control of pressure. The value of such a suggestion remains yet to be tested, however, and it would be futile to reason upon it at present. It might be a judicious venture first to tie the axillary or subclavian under the clavicle, and then if it were found that the aneurism still increased, amputation might be performed, either immediately before or after the separation of the ligature. But on this important subject I must beg attention to my remarks on the treatment of aneurism in the chapter on that disease, and also to the concluding observations in this chapter, where reference will be found to what I may humbly call my own views on such subjects, as elucidated in the practice to which I have given the term "manipulation."

I have now seen two instances of aneurism of the subclavian, in both of which ligatures were placed nearer the heart (in one case on the innominata, in the other on the affected vessel); and were a case similar to either to occur in my own practice, I should probably be inclined to follow the method above referred to, for assuredly the event could not be more disheartening than in these two examples.

The arteria innominata may be tied in the following manner:—The patient and surgeon should occupy such positions as are recommended
for the preceding operations, when an incision should be made between three and four inches in length, commencing over the middle of the upper part of the sternum, one inch or more below its margin, and passing upwards parallel with the inner border of the right sterno-mastoid. The skin, such of the fibres of the platysma myoides as are in the line, and the superficial fascia, should all be cut, and when the inner margin of the large muscle is exposed, the finger or a director should be passed under it, about half an inch from the sternum, and its fibres should be divided: next the cellular tissue should be separated, by slight touches with the knife, when the fibres of the sternohyoid will be exposed: this muscle and part or the whole of the sterno-thyroid should then be cut across, opposite the division already made in the mastoid; and now the vessel should be cautiously looked for in the cellular membrane opposite the upper margin of the sternum. Perhaps the lower part of the carotid may be first laid bare; but if it is, the main vessel cannot be far off:—by tracing the former a little downwards, the innominate will be reached, and the needle and thread should be passed around it, from below upwards, or as may be most convenient, about half an inch below the origin of the carotid. If the operator keeps low in the neck, the latter vessel, especially when the innominate is of considerable length, may not be observed, and unless it be from small veins, or possibly some small arterial branch, there can scarcely be any annoyance in the whole proceeding. A good deal on this score may, however, depend on the steadiness of the patient, the length of the vessel, and particularly the length and thinness of the neck. Although the operation must be deemed the most formidable which can be undertaken on the large arteries (unless, indeed, ligature of the abdominal aorta can be considered more so), it is by no means the most difficult, for under favourable and ordinary circumstances, and with moderate precaution, the surgeon can scarcely go wrong. There is nothing of consequence, excepting the veins already alluded to, lying over the vessel, and the vena innominate are usually sufficiently low to be out of harm's way. The right pleura, too, is so far under the artery, and the cellular tissue between them is so loose, that there need be little fear of this membrane suffering from the needle.

The incision above recommended is such as I have seen made on the living body; but, as with the operations previously described, I would not have the surgeon limit himself to one or other set course. Mr. Liston recommended that the incision should be made parallel with the left sterno-mastoid: for my own part, I should,—as has been stated elsewhere in this volume (p. 15), have more confidence in being able to appreciate the subcutaneous textures. A single perpendicular incision on either side, a transverse one, or a crucial, will be nearly alike useful to a competent anatomist: such as that indicated by letter d in figure 351 I should prefer; and, if I found the space limited, I should make a transverse wound in the course of letter c on the same drawing.

It was in an instance of aneurism of the subclavian above the clavicle that Dr. Mott first carried the bold idea into execution of performing
this operation. In a case where he intended applying the thread to
the latter vessel, he found, after exposing it on the inner side of the
scaleni, that the tunics were apparently so diseased as to induce him
to give up the idea, and (still anxious to afford his patient a chance of
life) he determined to place the ligature on the innominata itself,—an
alternative which he had at the commencement resolved to adopt,
should circumstances require it. Accordingly the artery was tied, and
the operation was all but successful: the patient, however, died on the
26th day, and such has been the result of all succeeding operations,—
some, as Graefe's case, living a longer period, others a shorter. Mott's
operation was done in 1818, Graefe's in 1822: the next was performed
by Mr. Norman, of Bath, in 1824, and singularly enough, there are few
British practitioners aware of the fact, although that gentleman was
long distinguished as an ornament to the surgery of this country.
Dupuytren alludes to an instance which occurred at Paris some years
back. In 1837 I assisted my friend Mr. Lizar in such a proceeding
(the case was published in The Lancet of that year), and another
example by M. Hutin is related in the same Journal for 14th May,
1842. In the latter instance the operation was performed for hemor-
rhage from the axilla, which was not effectually restrained by deliga-
tion of the subclavian outside of the scaleni: all the others were done
for aneurism in the vessel last named.

This operation has now been done some ten or twelve times, and the
results have been so unfortunate and discouraging as to induce any
reasonable surgeon to hesitate about repeating them. Yet it is difficult
to decide on such a question without having the specific case in view.
Mr. Porter (of Dublin) cut down upon the artery, but found it in
such a condition that he did not deem it advisable to place a ligature
upon it. The wound was therefore closed, when, strange to say, ere
long all pulsation in the aneurism ceased, as also in the innominata,
and ultimately the cure was complete. Professor Eve, of Nashville,
has collected an excellent history of all the attempts on this artery.
In the Pacific Medical and Surgical Journal for 1864 a successful case
of deligation of this vessel is recorded by Dr. D. L. Rogers. The
operation was performed by Dr. A. W. Smith, New Orleans. The
common carotid was tied at the same time, and a month subsequently
the vertebral artery was secured for secondary hemorrhage.

During the winter of 1869, I had under my care, at King's College
Hospital, a case of well-marked aneurism at the root of the neck, on the
right side, which was supposed to be of the innominata. The tumour
seemed likely to burst near the end of the clavicle. Digital pressure
was applied over the subclavian and the first rib by relays of zealous
pupils, and in less than six weeks the tumour could scarcely be
detected. The patient soon left the house cured. The particulars
were published in The Lancet of 30th October the same year.

In modern times, an opinion has been extensively entertained, that
during these operations, as well as others at the root of the neck,
shoulder, or axilla, implicating one or more of the veins, the ingress of
air into these canals has occasionally been the cause of sudden death,
and since such an occurrence was first supposed to have taken place, between thirty and forty instances of the kind have been related, as having happened in the practice of Dupuytren, Wattman, Delpêch, Roux, Velpeau, Malgaigne, Warren, Mott, and other distinguished surgeons. Since the time of Wepfer (17th century), who first slew an ox by throwing air into the jugular vein, physiologists have been well aware of the danger from the admission of air into veins, and the subject has been noticed by Morgagni and others; but it was not until 1818 that the profession had proof of there being danger from such a cause during the performance of surgical operations. A case of the kind, however, occurred at that time to Dr. Beauchêne at the Hôpital Saint Antoine, in a patient from whose shoulder and neck that gentleman was removing a tumour, and ever since the attention of surgeons has been fully alive to the hazard. It has been supposed by some that the air has been taken into the wounded vein by a kind of suction of the right auricle of the heart, but most authorities on the subject seem to hold that it occurs during inspiration. It is difficult to understand how it happens on some occasions, for one would imagine that the weight of the atmosphere would be as likely to close the vein as to force any air into the orifice: probably the way in which a vein is held or dragged during an operation may predispose to the occurrence, and, as has been remarked by some authors, should these vessels be thickened in their tunics, so that they may not readily collapse when empty, there may be greater risk. Many different sounds have been described as having indicated what had happened—a hissing one, or a kind of guggle, seems to have been noticed most frequently. The occurrence is indicated partly by the sounds and partly by the sudden syncope which ensues when a quantity passes in. It is difficult to say how much air may produce fatal results; certainly a larger quantity than was supposed by Bichat, as was long since proved by Nysten. My friend, Dr. Rose Cormaek, who has ably inquired into this interesting subject, has expressed his opinion that the alarm on this score is greater than the occasion justifies, and conveys with Velpeau, that some of the cases which have been recorded as examples of the injurious effects of the entrance of air into veins, are of equivocal character,—a view which I myself am disposed to take. No surgeon, however, would willingly keep the orifice in a wounded vein open, and although, as Dr. Cormaek has shown, a few globules which may accidentally be admitted cannot do that harm which some have imagined, the danger should always be held in view.

Professor Wattman of Vienna, who has written a most elaborate treatise on this subject, which has been admirably analysed in Cormaek's Edinburgh Monthly Journal for August and September, 1844, recommended ligature of the veins in such cases, but, instead of eneireling the internal jugular, for fear of apoplexy, put the ligature on the side so as not to obstruct the circulation. A case of the kind, which terminated successfully, occurred to Wattman himself. It was remarked by this surgeon that the blood does not flow from the orifice on all occasions of such injuries, and were this so, I imagine that
closure of the whole wound and a little pressure would be safer practice than the ligature. In the generality of such cases, however, the sudden death of the patient renders all interference futile. I leave these remarks as in former editions, but extended experience induces me to doubt more than ever the reality of these cases. I have seen as many operations involving divisions and wounds of the great veins of the neck and axilla as most men, but have never yet seen a case of the kind.

Ligature of the common carotid may be required for many different reasons, such as hemorrhage from wounds or ulcers, vascular tumours about the head, face, or neck, examples of which will be referred to afterwards, and especially for aneurism in the main trunk or some of its large branches. It has been performed in cases of epilepsy and for headache, and some enthusiastic dissecting-room operators have even proposed that this vessel, or the internal carotid, should be tied in apoplexy!

Both carotids have been obstructed by ligature on the same individual. Mott tied both simultaneously, but the patient died within twenty-four hours. The result has, however, been more fortunate where a lapse of time has been allowed between the operations, as has been evinced in the practice of Kuhl, Mussey, and others. My friend, Mr. George C. Blackman, has paid particular attention to this subject, and has himself been one of the successful operators. Dr. B. favoured me with references to ten cases in which this operation had been performed in the United States, showing that nine had been successful, and also mentioned four others, making a total of fourteen cases (including those above named), with only one death in all!

Mr. Crosse was, on one occasion, called in to place a ligature on one of these vessels, the other having been secured a short time previously; but on trying pressure on the vessel, the symptoms became so alarming that he did not interfere. I am inclined to think, with all due deference to such an authority, that pressure with the fingers produces effects very different from a ligature, and that therefore such a mode of testing the immediate danger of deligation is not altogether to be relied on. A case illustrative of this occurred to me in the summer of 1841. Being about to place a ligature on the common carotid, some doubts were entertained as to the immediate results of the proceeding, in consequence of the singular symptoms caused by pressure in the course of the vessel. When the ligature was tightened, however, no similar complaints were made, and I conclude, therefore, that the peculiar effects of the previous compression in this instance were not dependent on the mere obstruction of the carotid.

When the surgeon has the option of selecting a part of the vessel on which to place a ligature, the upper third of its course is decidedly the most eligible, and here the operation may be done in the following manner:—The patient should be laid on his back with the shoulders a little elevated, and the head slightly turned to the side opposite to that on which the incisions are to be made. The surgeon, standing at the head of the table as recommended for some of the preceding
LIGATURE OF CAROTID.

operations, should commence the incision about an inch and a half below the pomum Adami, over the inner margin of the sterno-mastoid, and carry it upwards for three inches or more, in a line parallel with the fibres of that muscle. Such a line is indicated by letter e in figure 350. The skin, platysma myoides, and superficial fascia should all be divided to about the same extent, and when the above-named fibres are exposed they should be drawn slightly outwards, and then the cellular tissue forming the sheath of the vessels should be cautiously opened with the knife, opposite the middle of the thyroid cartilage: by sight and touch the artery will be recognised, and by a most careful application of the blade near its outer side, there will be room made for the introduction of the needle, which should be carried round with its point close upon the vessel, from without inwards, and then the operation may be completed as in other examples.

An expert anatomist may accomplish this proceeding without seeing any of those important parts which lie in close proximity. It may be different, however, for on many occasions the internal jugular has, from its great size, so overlapped the artery, that much care has been necessary to avoid it. Reference to the surgical anatomy in this situation will explain how this is likely to occur in consequence of the difference in size of this vein on opposite sides or in different individuals, yet it is very certain, as I have myself experienced, that the jugular may not be seen at all during the whole proceeding.

When the operator entertains any doubt about his locality he should immediately refer to some well-known object in the vicinity: thus, the sterno-mastoid, whose fibres will always be more or less distinct, may be looked at, and if those of the upper belly of the omohyoid be exposed at the same time, the vessel, which lies immediately behind the angle where these muscles cross each other, can scarcely be missed, particularly after some of the cellular tissue has been divided.

The par vagum should not be seen; but the proximity of this important nerve to the outer and posterior side of the artery should not be forgotten. The best method of avoiding it will be that already pointed out—viz., keeping the point of the needle close to the artery: by following this proceeding, too, and also carrying it from without inwards, the convexity of the instrument will be opposed to the vein, which, as the operator should know, lies close on the outer side of the carotid.

The sympathetic is invariably so far behind and so loosely connected with the posterior surface of the sheath, that it is scarcely possible to imagine an instance where it could be included in the ligature.

Perhaps the greatest trouble in the operation will be from some small artery or vein. Often one or more branches of the superior thyroid, which pass to the sterno-mastoid, are so large as to bleed freely at first: if these give the least annoyance and cannot be commanded by the fingers of assistants, or by broad spatule (which may be used to keep the wound open), one or more forceps like that de-
picted on page 36 may be applied, or ligatures may be used at once, and the same practice might be adopted in case of hemorrhage from small veins, which sometimes run across the course of the incisions. If there is an anterior jugular, it, should be held aside with a blunt hook.

If the ligature is applied at the point above directed, it will probably be about half or three-quarters of an inch from the bifurcation; a line or two higher or lower cannot make any material difference. But it often happens that the operation must be done much lower in the neck, and here it becomes more difficult. The external incision should be of a similar length, only lower down, yet still on the inner margin of the sterno-mastoid. The same tissues must be divided, and in addition the sterno-hyoid, and possibly also the sterno-thyroid muscles, must be partially or wholly cut across. In fact, the instructions which have already been given for finding the commencement of the subclavian, or for exposing the innominate, will answer equally well for this proceeding on the carotid. In the operations referred to it is recommended to divide the inner head of the sterno-mastoid; and were I operating on the lowermost part of this vessel, I should not hesitate about doing so, for doubtless this would greatly facilitate the remaining steps. In such an instance I should make the external incision exactly in the line recommended for deligation of the innominate; and if the operation were required on the left carotid, I should make a similar wound, parallel, however, with the sterno-mastoid of the corresponding side. Towards the root of the neck the jugular vein and the par vagum are but slightly attached to the artery, but the surgeon will do well to remember that both are close at hand. Here, as in the other operations above described, some minor veins may be troublesome; indeed, in all incisions at the root of the neck such as those under consideration, as well as for other purposes, veins, which from their magnitude would give no trouble in other regions, may give great annoyance here, in consequence of the distended condition into which they may be thrown during the irregularity of breathing and straining incidental to such proceedings.

In an instance where an aneurismal tumour is low down in the neck, it will be perceived that such an operation may be exceedingly difficult, as the deep incisions must necessarily be limited between the tumour and the upper margin of the sternum. By great care, however, the vessel may be reached without serious injury to the neighbouring parts. Mr. Porter successfully tied the carotid within the eighth part of an inch of the innominate, and Dr. Robertson, of Edinburgh, cured a large aneurism, occupying nearly the entire side of the neck, when it was with the utmost difficulty that space could be found between the disease and the sternum wherein to expose the root of the carotid. An operation under similar circumstances occurred in King's College Hospital, in which I followed the precepts laid down in the preceding pages. The sterno-hyoid and sterno-thyroid were freely divided, and the section of the inner margins of the sterno-mastoid was of great advantage.
LIGATURE OF ARTERIES.

It has appeared to me an exceedingly singular circumstance how it happens so frequently, that ligature at the root of the carotid should be, upon the whole, so successful, while deligation of the origin of the subclavian has been so unfortunate. Until within a very recent date it has usually been considered that secondary hemorrhage (which is so fruitful a cause of death after these operations on the great arteries) has always occurred from the proximal end of the vessels; but the idea is now gaining ground that this occurrence happens as frequently, if not more so, from the distal side of the seat of ligature; and certainly the post-mortem examinations of some of these operations on the large arteries at the root of the neck go to favour this view. Cases in the practice of Mr. Lizars, Mr. Liston, and others, might be brought forward in support of this doctrine, and the circumstance has been pointedly alluded to by Mr. Porter, in his published lectures on aneurism. The vertebral artery has probably had more to do with secondary hemorrhage in some of these cases than our predecessors imagined, as has been proved by the successful ligation of the innominate recorded by Mr. Smith, of New Orleans, and referred to at p. 544. The greater facility of retrograde circulation in the subclavian than in the carotid, will not, however, account for the unsuccessful issue of all the cases in which the former vessel has been tied on the inner side of the scaleni muscles, as death has usually occurred before the period at which secondary bleeding may be expected.

Professor Miller, of Edinburgh, in a most able paper in the January number (1842) of the London and Edinburgh Monthly Journal of Medical Science, endeavoured to prove that death has resulted in most of these operations on the great arteries of the neck, from inflammation of the lungs, and it cannot be doubted that such a condition has often been present on these occasions. It appears, also, from experiments on the lower animals, that the lungs become seriously affected after ligature of their carotids; and from what I have myself seen, I should, coinciding in the views expressed by Mr. Miller, strongly recommend the free use of the lancet in all such operations as those which have lately been under consideration.

In instances of aneurism at the root of the neck, whether in the innominate, the origin of the carotid, or of the subclavian, the operation of Brasdor may be put into practice, or the modification of it recommended by Mr. Wardrop. If, for example, the disease were supposed to be in the innominate, Mr. Wardrop would place a ligature on the carotid or on the subclavian,—one being obstructed, the other left to nature, and be guided by circumstances, whether at any future period he would perform a similar operation on the other vessel. Brasdor’s operation could be put into practice on the carotid, for here in an aneurism at its root the circulation might be completely arrested. On the other branch of the innominate, however, if the aneurism were supposed to be at its root, a ligature placed outside of the scaleni could only have the effect of partially obstructing or altering the course of the circulation; and this, therefore, would be Wardrop’s operation, the difference between the two modes being that, in the one
(Wardrop's) the entire column of blood is not intended to be checked, whilst this in a manner constitutes the chief feature of the other (Brasdo'r's). My limits will not permit me to say more on such operations, and I shall therefore only state that I should feel inclined, in some of those cases where the patient's prospects were otherwise desperate, to offer a chance of cure by ligature on the distal side of the disease. The first instance in which Mr. Wardrop himself operated, that treated by Mr. Evans, of Belper, and various examples occurring in the practice of Dr. Mott, my friend Mr. Fearn, of Derby, and other practitioners of note, all hold out some gleam of hope in such unfortunate cases. In the summer of 1841, I placed a ligature on the carotid, for aneurism of the innominata, but the patient did not survive sufficiently long to enable me to form a decided opinion as to the probable permanent effect of the proceeding on the aneurismal tumour. The case was published in the November number (1841) of the Edinburgh Monthly Medical Journal; and I may refer the reader to Mr. Wardrop's treatise on aneurism, published in 1828, in which the principles of this operation are detailed, and, in addition, to the article Aneurism, by the same author, in The Cyclopaedia of Practical Surgery. Distal pressure, as referred to at p. 544, must not be overlooked in these cases.

Whilst recognising the accidental displacement of a layer of fibrin, or of the whole clot, as a cause of a spontaneous cure of aneurism, the surgeon never thought of inducing some such displacement by any interference of his own. From various histories and facts which had come within my knowledge, I long entertained the opinion that he might possibly, by judicious manipulation of such a tumour, cause one or other of the displacements alluded to, and so, by altering the current of blood, bring about those changes which are well known to induce the cure of this formidable disease. In February, 1852, I applied this treatment in a case of aneurism of the right subclavian between the scaleni, where the tumour was about the size of a hen's egg. By some rough squeezing with the flat end of the thumb, I displaced as much of the fibrin as caused pulsation in the axillary, and all the branches below, to cease. The throbbing in the tumour diminished within a few days. Gradually, after the first five days, pulsation became distinct in the radial artery, and then in the humeral, but the axillary remained closed. The transversalis colli became distinctly enlarged about ten days after the above proceeding, and at the end of four months only slight pulsation was perceptible. For a further account of this case I may refer to my paper read before the Medico-Chirurgical Society of London, 11th November, 1856. In this example death ultimately occurred, but I subsequently succeeded in another instance, the particulars of which are also detailed in the paper referred to. A successful case, similar in many respects to these, has been published by Mr. Little, of Lifford, in the Medical Times and Gazette for May 23, 1857, and another of femoral aneurism, treated in a similar manner by Professor G. C. Blackman, has been reported in the American Journal of Medical Sciences for July, 1857.
I have not as yet alluded to any important irregularities in these great arteries. The subclavian has occasionally been seen in front of the anterior scalenus muscle. I have myself met with only one example of the kind in the dissecting-room. Mr. Lizar, in operating outside of that muscle, discovered the vessel lying in front; the case was published in the Lancet of the 9th of August, 1834. Mr. Liston, in placing a ligature on the subclavian at its origin, had considerable difficulty in exposing the vessel, and at the time, fancied from its depth, that it might arise from the left side of the arch of the aorta, and pass to the right, between the trachea and oesophagus, or even behind the latter tube; he afterwards found that it sprang from the innominate, only a little further back than usual; but, in truth, the vessel often does curve back in this situation. Irregularities in the origin and course of the right subclavian, such as those alluded to, have frequently been met with by anatomists, and Mr. Harrison refers to a case where the right subclavian, passing between the trachea and oesophagus, was opened by ulceration, occasioned by a fish-bone sticking in the gullet, when fatal hemorrhage ensued. The right carotid, too, has its irregularities. It has been seen originating from the arch of the aorta; and in such a case it will be perceived that it cannot be a guide either to the innominate or subclavian. The innominate, as already stated, may be long or short; and it was probably from the latter circumstance that a Leipzig surgeon, instead of tying the main vessel, as he intended, placed the ligature on the carotid and subclavian at the same time; it may give off the left carotid, as well as the two large vessels on the right side; and in such a case, besides the danger of wounding the branch going to the left, as it lies in front of the trachea, its origin might be exactly in the situation where the surgeon would wish to place the ligature. He might hesitate to apply it immediately above the left carotid, for fear of the circulation preventing or breaking adhesions in the seat of deligation; on the other hand, were he to place it below, he would dread the effect of arresting the flow of blood through both carotids and right subclavian at the same time. Considering how seldom this irregularity has been seen, it must be admitted that such an emergency as that now referred to will be rare indeed. Were such a case to occur to me, however, I imagine (thinking quietly of it at the present moment), that I should prefer obstructing all three. It has been shown that in the lower animals both carotids may be obstructed by ligatures at the same time, and there is reason to suppose that such a step might be hazarded on the human subject (p. 545). In the Medical Times for 8th June, 1844, a case has been alluded to wherein an Italian surgeon had, for aneurism of the innominate, applied ligatures to the carotid and subclavian at the same period. The patient died six days after, and it was then found that the left carotid and right vertebral had been obliterated previous to the operations, so that, for some time before, the arterial circulation to the head must have been maintained principally by the left vertebral.

By the kindness of Dr. Wishart, formerly of the hospital staff at
Fort Pitt, Chatham, I have had the opportunity of examining a beautiful preparation illustrative of the subjects just alluded to. A patient of Messrs. Hammond and Biddle, of Lower Edmonton, had a tumour in the site of the innominate, which was supposed to be an aneurism, and treated accordingly. The pulsations from being very distinct gradually ceased, and ten months after the patient died of consumption. On dissection, a mass about the size of a duck's egg was found in place of the artery, whose tunics had seemingly been dilated in all directions, into an oval pouch, which was accurately filled by compact fibrin, deposited layer after layer in such a manner as to fill the interior to a level with the lining membrane of the aorta. The orifice of the innominate at this part was dilated to about the diameter of a half-crown piece, and the arch of the aorta was also somewhat expanded. The fibrin occupied a small extent of the interior of the aorta, so as to cover up the opening into the left carotid artery. This vessel, with the right carotid and subclavian, was completely obstructed, and the circulation to the brain could only have been, in any considerable stream, through the left vertebral artery, both it and the subclavian being somewhat enlarged in calibre. We know, however, that obstruction of both carotids and vertebals at the same time produces death, if continued for a very brief period only (the exhibition of the experiment was a favourite subject with Sir Astley Cooper in his later years), and in operating on the innominate, it would assuredly be well, in case of irregularity or obliteration, to try the effect of compression on the vessel before tightening the ligature. If it appeared that the patient could not suffer the obstruction, then the surgeon might console himself, as Sir Charles Bell did when he came on the double femoral artery, by the reflection that he could not be held responsible for all nature's irregularities; and even in such a plight he might, for the time, at all events, bear in mind the remarkable ease already referred to at p. 544, where Mr. Porter, after exposing the innominate, and finding it diseased, gave up the idea of securing it with a ligature, in which, nevertheless, the artery afterwards became permanently obstructed, and cure of the aneurism in the subclavian was the result.

The external carotid, or some of its branches, occasionally require to be tied. When this artery itself is the seat of operation, the thread is usually applied immediately above or below the digastric muscle, and consequently after three of its chief branches have been given off. The operation may be performed as follows:—The patient being placed as for the preceding operations, and the surgeon occupying a similar position, a lunate incision should be made, extending between the mastoid process and the body of hyoid bone, in the line indicated by the letter f in figure 351; the skin, platysma myoides, and superficial fascia, should all be divided to about the same extent, when the lower part of the parotid gland will be brought into view near the posterior end of the incision: the margin of this gland should then be turned or drawn slightly upwards, and the anterior border of the sterno-mastoid will be distinctly brought into view: the digastric
and stylo-hyoid will now be exposed, and, by dipping a little deeper on the upper or lower margin of these conjoined muscles, the external carotid may be exposed just before it passes behind the substance of the parotid. There may be one or more small veins in contact with the vessel; but the needle may be passed in any way the operator finds most convenient. Several veins of considerable magnitude will cross the line of incisions, and these must either be divided or held aside. Even in such large arteries as the subclavian, the sense of touch, as I have experienced, does not always enable us to feel the pulsations of the vessel; and in such an operation as that now under consideration, the surgeon should trust more to his eyesight than to the point of his finger; indeed, its accomplishment must be deemed more difficult than ligature of the common carotid, in consequence of the smaller size of the artery, and I may also say the greater depth. Fortunately such a proceeding is rarely required. I have seen it done previous to removal of the upper jaw; but it may be considered a settled point that such a preliminary step is not requisite. In referring to the surgical anatomy of this artery, I have noticed an instance in which it was found in an unusual position, external to the digastric and stylo-hyoid muscles.

The superior thyroid has occasionally been tied in cases of goitre, by Walther, Langenbeck, and others. In such an instance the guide to the vessel would be its own pulsations near the skin, for unless it were ascertained by such proof that the artery was enlarged, and therefore, probably, a considerable source of nourishment to the morbid growth, the operation would be worse than useless. On this subject more will be found in future pages (570 and 571), as also a drawing illustrative of the enlargement both of the gland and the arteries which belong to it.

The lingual and facial arteries may be exposed at their roots; but such operations are seldom necessary. Mirault tied the right lingual, but failed in finding the left. The operation has also been done by Amussat. Many years ago I saw Mr. Liston in the Edinburgh Hospital apply ligatures to both lingual arteries, for enlargement of the tongue, but no benefit resulted. The anterior end of the incisions above described for the external carotid may suffice, but were I to attempt operations on either of these vessels, I should begin the incision a little further forward, and not carry it so far back—keeping it, however, much in the same line, and dividing the same textures, though not so extensively. The extremity of the great horn of the hyoid bone, and the posterior margin of the hyo-glossus muscles, I should take as the best guide for the lingual artery, and possibly the same parts, and the lingual nerve, might show the necessity of looking a little higher for the facial, where it lies below the under margin of the submaxillary gland. Were such operations demanded on the living body, they would, in my opinion, require a far greater nicety of manipulation, and a more complete knowledge of anatomy than might be necessary for exposing larger vessels.

Occasionally other branches of the external carotid may require
deligation, as for instance, in vascular tumours of the scalp, but no set rules seem necessary for such proceedings: indeed, in the generality of cases the vessels will probably be exposed by the wounds which have permitted the escape of blood. It has been ascertained, that the vertebral artery, notwithstanding its depth, has been wounded, and proposals have been made to secure this vessel through a wound similar to that for exposing the subclavian on the tracheal side of the scaleni muscles. It has even been said that this vessel has been thrice tied with success on the living body.

It remains to be proved whether the recent revival of the method of treating aneurisms by pressure shall be of any value in the neck, for since the introduction of the Hunterian operation, no other has been thought of in this locality, except those of Brasdor or Wardrop. Pressure, if applied according to the old-fashioned views, so as completely to arrest the circulation in a main artery, could never be applied with such effect in this region, but in accordance with the doctrines of Dr. Bellingham it might be possible in many aneurisms here to keep up modified pressure, so as in some degree to obstruct the circulation in certain vessels, and in the tumour itself. Such a plan, as already stated, constitutes the peculiar feature of Mr. Wardrop’s proceeding. If, for example, ligature of the subclavian artery on the outside of the scaleni may prove sufficient to cure aneurism of the innominata, it is just possible that digital pressure, or such a tourniquet as that devised by Bourgery for compressing the subclavian, might have an equal effect; at all events it might be worth a trial, especially as its judicious use for a time could cause no harm, nor would it preclude a cutting operation afterwards, if that should be found necessary. The danger (if any) in the one proceeding would be infinitely less than in the other. Certainly we could not be sanguine of the success of such practice, yet, considering how inefficient and dangerous the usual means are for treating aneurisms in this part of the body, as explained in a preceding page (542), any such method as that here alluded to is worthy of full consideration. The late Mr. Mackenzie Edwards, when in practice in Edinburgh, had a case of the kind, and a seemingly successful one in my own practice has been referred to at p. 544.

CHAPTER VIII.

DIVISION OF CICATRICES AND OF STERNO-MASTOID MUSCLE.
LARYNGOTOMY. TRACHEOTOMY. PHARYNGOTOMY. CESOPHAGOTOMY.
TUMOURS IN THE NECK, ETC.

The kind of operation which may be required in instances of deformity on the neck resulting from burns cannot easily be anticipated: indeed, no two cases will be altogether alike; and if anything is to be
effected the surgeon must be guided more by his own judgment and ingenuity, than by such rules as can be given here. I have seen many operations for such deformities, and have myself tried the efficacy of dividing bands of cicatrices, and sometimes removing them altogether, but cannot on the whole speak in high terms of such proceedings, although I have occasionally seen some excellent results. When a cicatrix has been removed, and the wound treated by bringing the skin up from the sides, so as to unite the opposite edges by stitches or straps, I have generally noticed that after the first few days the surface has gaped as much as when first made, and that after union by granulation had been accomplished, the parts were in much the same condition as before,—in some, perhaps, a little the worse for the proceeding. In instances when a cicatrix has been merely cut across, and where the head has been held in a favourable position for weeks, I have generally noticed that, at last, matters have arrived at nearly the same condition as when the knife was first used. I must admit, however, that all instances have not been alike unfortunate. I have no doubt that much might be done in the early treatment of burns in this situation as elsewhere, to obviate the contraction of the granulations. In the introduction (p. 95) I have referred to the necessity for keeping granulating surface in a proper attitude lest deformity should occur in the progress of cicatization, and a case is detailed illustrative of the continued tendency to that result, even after the latter process is apparently complete.

Mr. James, of Exeter, was successful in treating such contractions and deformities in the neck by a kind of collar, which is so constructed that the head can be supported by means of a screw, and the cicatrix is at the same time kept on the stretch until the tendency to contraction has gone off. My friend, Mr. May, of Reading, has also tried this plan with some advantage. Mr. Carden, of Worcester, has published in the twelfth volume of the Transactions of the Provincial Medical and Surgical Association, an interesting case of deformity resulting from a burn in front of the neck, which he treated with great advantage by dividing the cicatrix and bringing into the gap two flaps of sound skin taken from the vicinity, and my friend, Professor Mütter, of Philadelphia, has been remarkably successful in similar cases by placing one large flap, taken from the skin over the shoulder, and adjusting it in its new place by stitches. Professor Pancoast, of the same city, has also been equally happy in similar instances, and the practice seems to me to be well worthy of further trial in this country.

Whilst this page is in the printer's hands, some novel excitement prevails in the profession regarding the proposals and experiments of M. Reverdin, for transplanting small films of skin, little more than the cuticle, from healthy surfaces on to such granulating sores, here and in other parts of the body, when cicatization proceeds but slowly. Mr. Pollock, of St. George's, has drawn attention to the subject in this country, and already an impression has arisen that much good may come from the practice. It reminds one forcibly of
the good and rapid results which we see from time to time when islands of cuticle appear on large granulating surfaces. Some interesting observations, as being the earliest in this country, on the subject, will be found in The Lancet for 25th June and 9th July, 1870.

Of late years, since subcutaneous incisions have become so common, the sterno-mastoid has been frequently cut across for the cure of wry-neck (torticollis) by such a wound. Formerly, in dividing this muscle, or any portion of it, the custom was to expose the fibres through an incision on the surface, and afterwards to complete the proceeding on a director; now, however, it can scarcely be doubted that a subcutaneous wound should be preferred, and the operation may be done as follows:—The muscle being put on the stretch, a narrow blade (fig. 352) should be passed flatwise behind its inner margin to such an extent as may be deemed necessary, when the edge should be turned upon the fibres, and their division effected by cutting towards the skin. It would be well in most instances to slip a director behind the muscle, and to keep the blade in its groove. Perhaps the incision of the sternal portion of the muscle may suffice; but in most instances the clavicular portion must be divided also. If the operator is cautious in not pushing the knife too deep at first, there can be no danger in the proceeding just described; but every anatomist may foresee what might happen from carelessness here. The blade may be first passed below the skin only, and then thrust against the muscle; but if this method is chosen, care must be taken that the knife does not plunge deep when the division of fibres has been effected. After the operation, a pad should be placed over the little wound in the skin and the space between the retracted ends, and subsequently the case must be treated according to circumstances. If the distortion has previously been slight, possibly no particular apparatus may be requisite; but, in general, as in the instance of club-foot already referred to, some mechanism, such as has been represented by Benjamin Bell and others, should be applied, for the purpose of keeping, or rather bringing, the head into a proper position.

Laryngotomy may be effected through an incision about an inch long, in the mesial line between the pomum Adami and the lower margin of the cricoid cartilage. The crico-thyroid membrane may be exposed almost immediately below the integument, the blade passing between the two sterno-hyoid muscles, and if the subject or patient be thin, the depth of the wound will be trifling. When the membrane is exposed, the point of the knife should be thrust into it with a kind of jerk, and the requisite extent of incision made—sometimes in a vertical line, at other times in a horizontal, or, in some instances, in a cruciform direction, according to circumstances.
Tracheotomy may be performed thus:—The chin and sternum being well separated, an incision through the skin, about an inch and a half or two inches long, should be made with a scalpel, extending from near the upper margin of the sternum to the cricoid cartilage; then the cellular tissue at the lower end of the wound should be cautiously divided, the operator keeping a sharp look-out for veins that may be in the way, so that they may be held aside, when by keeping in the mesial line, the trachea will be exposed a little below the isthmus of the thyroid gland. The point of the knife should now be passed into the tube at the lowest part of the exposed portion of the trachea, and carried from below upwards to any desired extent.

It may happen that these proceedings when required on the living body will be accomplished with as little trouble almost as on the dead; but it will often be otherwise; and many circumstances may be connected with them which will call forth much of the skill and coolness of the operator.

Laryngotomy is but rarely performed compared with the operation on the trachea, and the cases are few in number in which the proceeding seems to possess any advantage over the latter: indeed, it is scarcely possible to name an instance. The principal necessity for either operation is to allow the patient to breathe more freely, whilst occasionally an opening is required to give egress to a foreign body, which may have accidentally passed into the larynx, trachea, or one or other of the bronchi. Such a body may be the cause of the difficulty in respiration, or this condition may be the result of inflammation of the mucous membrane; but unless there is a special reason for dividing the erico-thyroid membrane (such as the ascertained lodgment of a foreign substance in the larynx, or the shortness of the neck, as in an infant), the operation of opening the trachea is most generally preferred.

In Laryngotomy, the only casualty at all probable is the division of a branch of the superior thyroid artery (erico-thyroid), which runs across the membrane, and is occasionally of such size as might cause trouble when cut. The late Professor Turner, of Edinburgh, used, in his lectures, to relate an instance where, in such an operation, a child bled to death from a wound of this vessel. Possibly the division of the membrane between the cricoid and thyroid cartilages may not leave an opening sufficiently large, and it will, therefore, be requisite to carry the knife upwards or downwards. If the thyroid cartilage be cut, there is a probability of one or other of the vocal cords being divided, unless the incision is exactly in the mesial line: if the wound is extended downwards no serious harm can result; but it should be remembered that the aperture in the cricoid cartilage will not gape like that in other parts, for the strength and elasticity of the ring is such that the cut surface will continue in contact unless they are held asunder. In a young subject the chief difficulty in the operation seems to be in the recognition of the parts after the wound on the surface has been effected, from the smallness of their size, and this difficulty may be greatly increased if the skin and cellular tissue be
inflamed and infiltrated with serum, in consequence of the previous application of leeches, sinapisms, and blisters.

In Tracheotomy the casualties and difficulties may be more numerous and greater. It may be the case that the parts over the trachea are much swollen, from the circumstances alluded to above; but besides this, the tube is always much deeper in the neck than the larynx, and if the patient is fat, muscular, short-necked, and unsteady, there may be great trouble in the operation. The isthmus of the thyroid gland is generally more or less in the way, but unless it be enlarged there will seldom be much trouble from the bleeding which may result from its division: if there were sufficient room below to keep clear of it I should certainly do so, but it should always be borne in mind, that in avoiding this evil and getting near the sternum, others of a more serious nature are encountered:—the subcutaneous veins increase in size towards the root of the neck, and if wounded low down the blood might regurgitate from them: possibly the left vena innominata might bc in the way, although this is not likely, for it is generally below the level of the upper margin of the bone: the arteria innominata, or the right or left carotid, may, as already referred to at p. 551, be so high in the neck as to be in danger. Hence then the propriety of passing the tip of the finger to the bottom of the wound to protect the parts in this situation, and also the wise precaution of introducing the point of the knife with the back nearest the sternum and cutting upwards: for, by these proceedings, although the edge of the instrument may come in contact with the thyroid gland, it is the least of the evils that have been under consideration. The necessity for keeping in the mesial line cannot be too carefully attended to: in the upper part of the trachea, a slight deviation may endanger one of the lobes of the thyroid, from which the bleeding would assuredly be much more profuse than from the isthmus. In an instance occurring in my own practice, where the patient, a short stout-necked female, was remarkably unruly, I got a little to one side, and the bleeding was very copious. In the lower part of the neck the danger may even be greater, for the carotids lie closer to the tube than towards its upper end. A case has been mentioned by Desault in which the carotid was opened, and where of course death ensued.

I have seen Trachcotomy performed when a quarter of an ounce of blood did not escape; but in most of the instances which have come under my notice the hemorrhage has been remarkably free. Sometimes this has apparently arisen from the inflamed state of the textures over the tube, in other instances from the distension of the smaller veins, produced by the derangement in respiration, and occasionally from the vascular condition of the mucous membrane.

A variety of circumstances must guide the surgeon in giving preference to one or other of these operations,—in selecting a place at which to open the trachea, and in the manner of conducting the proceedings.

As already stated, there are few reasons in favour of Laryngotomy,
and excepting the suspicion that a foreign substance is impacted between the vocal cords, I know of no other inducement to select this proceeding in preference to Tracheotomy, unless, indeed, it be that the crico-hyoid membrane is more superficial than the trachea. Cherry-stones, plum-stones, kernels of fruit, beans, kidney-beans, small pebbles, buttons, coins, and such like objects, which children may inadvertently allow to pass the rima glottidis, may lodge in the ventricles of the larynx; and might be more readily displaced by having the opening near. A fish-bone has been known to stick across the larynx, and La Martinière has related a case where a large brass pin, which had been attached to the end of a boy's whip, was, in cracking the toy, forcibly driven across the larynx, from whence it was extracted by making an incision through the skin sufficient to permit of its head being seized, where it was sunk deep under-neath.

Whether an opening be required for oedema of the rima glottidis, for ulceration connected with the upper orifice of the larynx, for croup, or for the removal of foreign substances from the bronchi or trachea, the incision is almost invariably made in the latter tube. In the first of these conditions above named, the opening is required to allow respiration to go on; in the next, partly with the latter object, but more particularly to allow the ulcers to remain at rest,—at least so some have argued; and in croup to admit of more free respiration, and also for the escape of mucus (perhaps of false membrane) from the trachea and bronchial tubes.

In asphyxia, from whatever cause it may arise, and when it is resolved to open the air passage in the neck, it is evident that there is no time to lose, and therefore the surgeon should complete the operation at once without heeding the hemorrhage; however copious it may be: the patient has no chance of life unless respiration is restored, whereas experience has shown that death from hemorrhage in such proceedings is extremely rare. It is generally recommended that in doing this operation the wound in the trachea should not be made until all bleeding has ceased; but although it is satisfactory to see that such is the case, it would in some instances be highly improper to wait. Mr. Porter states "that it has happened that a patient has been lost whilst the surgeon delayed the opening into the trachea in order previously to control an alarming hemorrhage." An erroneous impression obtains with some, that the interior of the trachea is as exquisitely sensitive as the upper orifice of the larynx, where a drop of water cannot touch without producing a paroxysm of coughing; but experience in these operations has shown that the lining of the windpipe possesses as little of this peculiar delicacy as most other mucous canals. A few drops then, or indeed any quantity, so that it does not impede breathing, may pass into the tube through the wound with impunity, as it will be expelled again as soon as its presence causes annoyance. Indeed, without wishing to detract from the danger of bleeding, I nevertheless doubt if any one ever died from internal hemorrhage on these occasions: I have myself seen blood
flow freely into the trachea from such wounds, but it has been speedily and as freely ejected again, and, for my own part, the bleeding which I should most dread would be from a copious flow externally. If half an ounce or an ounce of blood was to flow into the trachea, unless the patient were exceedingly exhausted, he would be sure to expel it again by the wound or by the upper part of the tube. Hemorrhage should induce the surgeon to examine the surface of the wound, when if the bleeding vessel is of any considerable magnitude he will discover it at once, and if it is an artery a ligature can be applied, or if a vein pressure may suffice. But even in the case of severe hemorrhage the blood is much more likely to flow through the external wound than into the trachea, and in illustration of this, I may refer to a case related by Mr. Porter, who was called in hurriedly, after tracheotomy had been performed by another surgeon, as the patient was stated to be bleeding to death. He found him sitting on a chair, blood profusely flowing from the wound, and a coagulum on the floor at his feet "as large as a liver," to use Mr. Porter's own words, yet even in this case there does not seem to have been any bleeding internally, and that on the surface was speedily arrested by pressure.

I have recommended a knife wherewith to make the opening, but some have preferred a trocar; and one of a particular shape, such as that represented in fig. 353, has actually been made for the purpose, being, in addition, fitted to a canula which may be allowed to remain in place of the tube alluded to afterwards. For such a purpose, however, this canula seems too narrow. It requires a little dexterous management to introduce even the sharp point of a scalpel in some of these cases, and I should consider it much more troublesome to cause the clumsy point of the other instrument to pass with facility. The rings of the trachea, and also the fibrous intervening membrane, are so dense that in the young subject they will sink before the point, until the opposite sides almost meet, and even with the scalpel a kind of plunge, or jerk as I have previously called it, is necessary at this stage of the operation. Possibly seizing the trachea with hook-beaked forceps (p. 31), or with a tenaculum (p. 32), might facilitate this step of the operation.

If the opening is intended to allow the patient to breathe more freely, it will be necessary to make some provision to keep it patent. Some portions of its margins may be cut away with this object, and such a proceeding has been frequently done; indeed, Dr. Marshall Hall, who took great interest in this operation as a means of arresting the convulsions of epilepsy, proposed that an instrument should be
used in opening the trachea, which might cut out a circular portion of
the tube at the time; but in general it will be best to introduce a
silver tube of the shape here represented (fig. 354), and to retain it
by tapes, attached to the rings, suffi-
ciently long to join at the back of the
neck. Such an instrument is useful
for the purpose referred to, and may
be serviceable too by its pressure in
arresting bleeding,—indeed, in cases of
venous hemorrhage it may be of great
advantage, whether by itself or partly
surrounded by lint. I have seen some
trouble in passing this tube, both in
Laryngotomy and Tracheotomy, owing
to the elasticity of the ericoid cartilage or the rings of the trachea:
the edges, therefore, require to be held asunder by hooks or forceps
until the point is fairly inserted. But before this can be
attempted it is necessary, in many instances, to hold the
wound open to permit the egress of mucus which may
have accumulated in the trachea and bronchi. In group,
when such an operation is performed, the necessity for
this is very evident, so that both mucus and lymph may
be allowed to escape; but the same may exist in other
instances. Occasionally it has happened that unless
means had been resorted to to promote the escape of
the contents of the trachea, the patients would have
perished. Mr. Porter related an example of the kind
where one of his assistants emptied the passage, by placing
his lips over the wound and applying suction, and another
where a syringe was used with an equally good effect.
A most ingenious instrument for opening the trachea was
exhibited at "The Great Exhibition of 1851," by some
of the foreign makers, which seems worthy of special
notice here. It is the invention, I believe, of M. Garin,
of Lyons. In shape and size it resembles common
forceps, with the exception that the one blade is bent at
the point, as may be seen in this figure (355): the blades
when shut are about the size of a small scalpel, and one
is so sharp at the point—and on one side, that it will
readily pierce and cut the trachea, whereupon they may
be allowed to open, when they will hold the sides of
the aperture asunder for the various purposes of the
operation.

In many instances, even after the tube has been intro-
duced, the accumulation goes on so rapidly again that it
is requisite from time to time to clean it with a feather
or a piece of lint on the end of a stick or probe; and
at all times it is necessary to be careful that the tube
does not slip out, or that it is not removed at too early a period.
have seen at Weiss's an ingenious double tube for such cases, one fitting within the other in such a manner that it can be withdrawn from time to time as occasion may require, while the other remains in the wound. Indeed, it is advisable in all such proceedings to have, if possible, several tubes of different sizes, shapes, and lengths.

Of late years a great improvement has been made by a slight modification of the external tube. Instead of having actually a tube, it consists of two sides with a considerable space between, as seen in this figure (fig. 356). When these blades are squeezed together, their ends are like the point of a wedge, and they slip into the wound in the trachea with marked facility. Being elastic, they expand and actually open the slit in the trachea, and this expansion can be increased by introducing between the blades the tube intended for respiration (fig. 357). This latter tube can be taken out and cleaned at will, and introduced again, without disturbing the patient. This inner tube may have only two openings, one at each end, or there may be one at the upper part of the curve, whereby air or mucus may escape more readily. Sometimes this inner tube more resembles a coil of wire in a part of its length.

In one of my patients in the Edinburgh Hospital, difficulty of breathing (from disease in the larynx), came on so suddenly one evening, that ere my house-surgeon, Dr. David Williamson, could be at the bedside, asphyxia had ensued. With great promptitude, however, that gentleman made an orifice in the trachea, applied his mouth and forced some air into the lungs, which he immediately forced out again by pressure on the abdomen and chest, when happily, after a repetition of one or two such manoeuvres, the patient breathed for himself again, which he continued to do, partly through the orifice and partly through the larynx, for many weeks, until he at last died from disease of the chest.

The tube must be worn as long as there is a necessity for it, and this period will vary in different cases according to a variety of circumstances. As soon as it can be dispensed with so much the better, and the wound will in general close of its own accord. Sometimes, however, it does so but slowly; occasionally it continues open ever after, and the patient when about to speak has to place the point of his finger on the orifice in order to throw the current of air between the vocal cords. Caustic, the cautery, or even paring the edges with a knife, may be resorted to with advantage. I once saw my former colleague, Mr. Watson, cut the edges of the orifice, bring them together with a twisted suture (taking care, however, not to separate the skin,
for fear of emphysema, and also not to pass the needle into the trachea), and succeed in closing the aperture permanently. In some instances the larynx never resumes its normal condition, and in these, if the orifice in the trachea shows any disposition to close, and respiration through the larynx becomes difficult, it will be necessary to introduce the tube again. I saw an interesting example of this, some years ago, in the practice of Mr. Henry Smith (who has had considerable experience in tracheotomy), the particulars of which will be found in a paper by that gentleman in the Medical Times for 9th July, 1853.

When Tracheotomy is performed for the purpose of removing a foreign substance, which has passed through the larynx downwards, it will in general be necessary to introduce instruments to assist in this object. Such cases have been most frequently seen in children, although accidents of the kind occasionally occur in adults. Stones of fruit, pebbles, small coins, and the like, as previously stated, may slip between the vocal cords, and lodge immediately below, or in one of the bronchial tubes—generally that of the right lung—or may move upwards and downwards between the bifurcation and the rima glottidis. The history of such cases usually explains what is wrong: at first the patient may have been almost suffocated as the object has passed into the larynx, then he may have had severe fits of coughing, which may suddenly have ceased and as suddenly begun again; these symptoms, coupled with the knowledge that a foreign body has passed backwards from the mouth, will go far to show the cause of the paroxysms; but the stethoscope may aid greatly in the investigation.

It has happened in some of these cases that as soon as the opening has been made the substance has been forcibly expelled through the wound, and hence the propriety of keeping the margins of the aperture in the trachea asunder by means of hooks; but there has more frequently been a necessity for the introduction of instruments, and such a one as that represented at page 490, for the extraction of polypi from the nostrils, has been used on these occasions. The blades beyond the hinges should be somewhat longer than those referred to, and the whole instrument must be adapted, both in thickness and length, to the age and size of the patient about to be operated on. These must be passed upwards or downwards, as may be required: if upwards, probably the blades may be kept shut, and used as a kind of probe to push the substance through the upper part of the larynx; and if downwards, they must be opened with the purpose of grasping the object to be removed. The forceps represented in fig. 361, p. 569, answer well for this part of the operation.

Mr. Porter, whose admirable work on the Larynx and Trachea cannot be too highly extolled, related many remarkable cases of the extraction of extraneous bodies from the air passages. Dr. Houston detailed an instance where a large molar tooth with its fangs entered the trachea; Mr. Key opened the trachea for the purpose of extracting a coin from the right bronchus; I once saw Mr. Liston most adroitly and successfully extract a portion of bone from the right bronchus (the case is
referred to in his excellent work on Practical Surgery), and a somewhat unusual instance of the kind occurred to myself. A girl, seven years of age, in reaching her hand high above her head, inadvertently let a plum-stone which she had in her mouth slip backwards, when it entered the larynx and immediately produced most severe coughing and occasional obstruction to respiration. My friend Mr. Stuart, of Kelso, saw the case, and proposed Tracheotomy, which was accordingly performed. Owing to the impossibility of keeping the patient quiet, the object could not be seized, and, from the injudicious interference of the friends, it was found necessary to give up any further attempt to do so. The wound closed, and the girl continued to suffer as before: at times she had some rest, but often, and suddenly, she would drop on the floor in a state of asphyxia, from which condition she would recover after a violent effort at inspiration. Three months afterwards she came under my charge, but seemed so alarmed at the approach of medical men, that I almost despaired of being able to attempt anything for her relief. By kind management, however, she was induced to submit to another operation, when I succeeded in extracting the plum-stone. Before the proceeding, it had been ascertained that the object moved between the bifurcation and upper end of the trachea: this was most distinctly noticed when the forefinger and thumb were placed one on each side of the larynx, for then, if she was desired to cough, the impulse of the stone was felt as it struck the narrow part above. Dr. Henderson and the late Dr. Spittal (both well known at the time as accomplished stethoscopists), who examined the case with me, felt more satisfied in this way than by auscultation. After making the wound in the trachea, I introduced a slender pair of forceps, similar to those already recommended, and for a time was unsuccessful in my object: the stone seemed to move upwards and downwards alongside of the blades, and at last, under this impression, and at a time when I imagined that it was at the lower part of the tube, I opened the blades and held them so until the next expiration, when I closed them suddenly and caught the object, which was then extracted with a slight pull. Immediately all annoyance ceased; the wound closed almost entirely by the first intention, and every danger being apparently over, the patient, eleven days after, was permitted to go into the country. Here, however, she seemingly had caught cold, and three weeks afterwards she died of difficulty of breathing, occasioned, from what I could subsequently learn of her history, by swelling of the mucous membrane of the larynx.

A most interesting case of a foreign body (half a sovereign) lodged in the air-tubes, was communicated by Sir B. Brodie to the Royal Medico-Chirurgical Society, and published in the twenty-sixth volume of the Transactions. The coin, it was ascertained, passed upwards and downwards between the right bronchus and the larynx, and hopes were entertained that by permitting the patient’s head and shoulders to slope downwards, the coin might slip through the rima glottidis into the mouth. The position, however, invariably brought on severe and dangerous coughing. Tracheotomy was performed,
PHARYNGOTOMY. ÖESOPHAGOTOMY.

and an attempt was made to seize the object with forceps, but with no success, for the lining membrane of the larynx would not bear the contact of the instrument. Ten days after,—the wound in the trachea being kept open during the interval,—the patient was placed with his head downwards as before, when by tapping on the back between the shoulders (a manoeuvre which had been found previously to be of service) the coin moved from the bronchus and speedily struck the incisor teeth of the upper jaw. All annoyance ceased, and the wound rapidly closed.

A case of a somewhat similar kind occurred to the late Dr. Duncan, of Edinburgh. A shilling had passed into a man's larynx, where it seemed to have stuck fast; the head and shoulders were suddenly thrown downwards by several stout assistants raising the waist and pelvis, and while another handled the larynx somewhat roughly the coin dropped on the floor. The particulars of this case may be found in the second volume of The Northern Journal of Medicine. No preliminary opening was made in the trachea, but Dr. Duncan was prepared to make one, had any difficulty of breathing arisen in consequence of change in the site of the object in the larynx. Fortunately, however, there was no occasion for such a step. These two examples clearly indicate the propriety of trying the effect of change of attitude in such cases, for when we reflect how often persons have died in consequence of the presence of foreign bodies in the air passages, and how, too, occasionally such bodies have been spit up after months or years of almost continued coughing and suffering, it is not unreasonable to suppose that such a change of attitude, and some such additional measures as were resorted to by the gentlemen who conducted the treatment of the two instances above referred to, might have saved many lives. Two instances have within the last few years come under my care, where foreign substances were known to be in the root of the bronchi. One was a glass bead. The symptoms never in my presence were so severe as to induce me to interfere, and ultimately after many months the object suddenly escaped by the larynx and mouth. The other case seemed to me of a like kind, and here I have "let alone" also, but I have not yet heard of any result.

It is scarcely necessary for me to mention that, after such an operation, the wound should in general be closed at once. In Tracheotomy for difficult breathing, the opening is made with the object of allowing the patient to breathe through it: but in the instances last alluded to it has been made only for the convenience of removing the foreign substance.

My limits will not permit me to dwell longer on these subjects; but I cannot avoid again drawing attention to Mr. Porter's treatise, in which numerous cases illustrative of the affections of the larynx and trachea will be found, accompanied by practical remarks, which are additionally valuable, coming as they do from such a source.

Pharyngotomy and Oesophagotomy are very rarely required. It is customary for the anatomist to notice that the gullet lies a little to the left of the trachea, and in cutting into it on the dead subject this side
is always selected: the proceeding may be done in the dissecting-room as follows:—A portion of bone, bit of muscle, or other convenient substance, should be pushed into the lower part of the pharynx, until it is made to bulge in the neck, which it will probably do most conspicuously on the left side of the thyroid cartilage; then an incision through the skin, between two and three inches long, should be made over the swelling, when the platysma, cellular tissue, and gullet, being divided, the object will be uncovered, and must next be extracted by means of hooks or forceps, as may be most convenient. Here it will be observed, that the wound will probably enter the lower end of the pharynx instead of the oesophagus; but similar instructions will enable the student to cut into any part of the latter tube above the root of the neck, although it must be evident that there are many objections to attempting such a proceeding on the living body. Opposite the larynx the incisions pass between that part and the common carotid: the latter vessel is so near that it must be considered in danger, and in all probability the superior thyroid artery would be cut, whilst the superior laryngeal nerve would possibly meet the same fate. Towards the root of the neck the carotid would be nearer to the course of the knife; the thyroid gland, the inferior thyroid artery, and perhaps, too, the inferior laryngeal nerve, would all be in danger: in short, simple though the operation may appear on the subject, I consider it attended with great danger on the living body, and would proceed about it (if ever called upon to undertake such a proceeding) with the utmost caution: I should examine every texture before applying the knife, and after making a small opening in the tube, would probably use a probe-pointed bistoury to enlarge the aperture.

On the dead subject, in making the incision above recommended, it will be an advantage to introduce a steel bougie through the mouth into the pharynx, the point of which can be made to project into the wound of the neck: such a proceeding might also be of service on the living, more especially if the foreign substance did not project much.

Sometimes, instead of cutting on the projection, it might be deemed advisable to make the opening below or above, so that the offending substance should be pushed upwards or downwards, as circumstances might indicate: if upwards, perhaps the finger introduced through the wound might answer; but if downwards, an oesophagus bougie would be required. It seldom happens, however, that, when an object has once passed the upper end of the gullet, it does not readily find its way to the stomach.

In my own experience I have only seen one instance in which it was proposed to perform Pharyngotomy or Esoophagotomy. A girl about twenty years of age came under the care of Mr. Lizars in the Edinburgh Hospital, who was said to have swallowed a small padlock, which she asserted was lodged in her throat. The most careful examination by means of the finger, steel sound, and probang, gave no indication of its actual seat, and only on one occasion, during the
different consultations which were held on the subject, was there any evidence that the object could be touched by the instruments introduced for the purpose: the sound seemed undoubtedly to indicate the presence of the metallic substance; but upon another trial it was observed to strike against the incisor teeth, and as the point could not again be brought in contact with the padlock, the idea of making an incision in the neck was abandoned for the time, more particularly as there were reasons for supposing that the person was an impostor. As she, however, still asserted the truth of her first story, she was kept in the house, and some time after, during the night, the house-surgeon was suddenly called to her in consequence of a severe fit of vomiting: during an effort he introduced a large pair of forceps into the pharynx, and at once seized the padlock, which he removed without the least difficulty. Whether it had ever been in the stomach it was impossible for any one to say,—certainly there were no marks of the gastric juice having acted upon it, although three weeks had elapsed from the time when it was said to have been swallowed.

A case of an unusual character was communicated to me by the late Dr. Little of Sligo, wherein a gentleman, during an epileptic fit, swallowed five false teeth with their gold setting. About after four years and a half death occurred from a bronchitic attack, and on examination, the teeth and setting were found at the lower part of the pharynx, the semicircular plate of gold surrounding and distending the top of the oesophagus. Dr. Little had been deterred from attempting any operation under the dread of causing fatal laceration. A most interesting case of a somewhat similar kind has been related by Dr. Duncan, of Edinburgh, in The Northern Journal of Medicine for May, 1844. In this instance the sharp point of the metallic setting caused ulceration in the oesophagus, opened into the arch of the aorta a little beyond the left subclavian, and caused fatal hemorrhage on the tenth day.

In certain instances, when a foreign body is known or supposed to be in the gullet, the best practice may be to push it down altogether with a broad-pointed bougie or probang, especially if it be in the lower end of the tube; but, if it is within reach, attempts should be made to remove it by the mouth. The instruments to be used on such occasions must be selected according to circumstances. Perhaps a probang with an ivory knob at the end, like this (fig. 358)

Fig. 358.

may be serviceable, or a bit of sponge on a slender stalk of whalebone may prove equally useful in pushing the object down; or it may be hooked up by a contrivance like this (fig. 359—the book being with
THE HEAD AND NECK.

or without a hinge as here represented); or, what would be better, it may be seized with forceps, as displayed in figure 361, and so ex-

\[\text{Fig. 359.}\]

tracted. Many years ago, a most ingenious surgeon in Kelso, the late Mr. Robertson, invented an instrument somewhat like a bottle brush, enclosed in a sheath or tube, like a stomach tube, with which he proposed to sweep the esophagus, just as the modern Ramoneur is used in vents.

\[\text{Fig. 360.}\]

An interesting paper from Mr. George Pollock on such subjects appeared in The Lancet for April, 1869; and in May of the same year a case was recorded in the same journal by Dr. Bond, of Parliament-street, of a patient who had, during delirium, swallowed a brace buckle an inch and a half in length, and one and a quarter in breadth, with the attached leathers, each four inches long. These had stuck in the gullet, within two or three inches of the stomach, for many days; and after various attempts by Mr. Wood and myself to seize and draw them upwards with long forceps, I pushed them downwards with a probang (fig. 358), to the immediate and permanent relief of the patient. There has been no further knowledge of either straps or buckle. Not long ago a female was sent to me after having swallowed four false upper front teeth, with gold setting. I detected them near the lower end of the gullet, and pushed them with a bougie into the stomach. In four days after the patient reappeared, proudly displaying the teeth again in her mouth. Meanwhile, they had travelled, without check or hindrance, the length of the intestines, when, being carefully looked for and found, they were immediately replaced, to resume their original ornamental duties. After such a strange passage I thought that the patient would relinquish them for a new set, but she preferred them as lost and found cherished friends. In The Lancet for the 12th March, 1870, I published a short paper on "Swallowing Indigestible Substances," in which I referred to some famous cases of the kind, particularly to that related by Dr. Marcet, of a man who died in Guy's Hospital, after having swallowed, in the course of ten years, thirty-five clasp knives, and other indigestible substances. The chief object of that paper was
to record the swallowing of a gold pencil-case four inches and a quarter in length (fig. 360), which a patient of mine had swallowed,

*Fig. 361.*

and parted with *per annum*, after the lapse of twenty-two days. No evil of any kind resulted.

It is often necessary to introduce bougies, probangs, stomach-tubes, and other instruments into the pharynx and oesophagus, and it may be stated generally, that, with few exceptions, it is always best to allow the patient to keep the tongue within the mouth when it is desired to introduce any object into the pharynx or gullet. Sometimes it may be necessary for the surgeon to depress the root of the organ with the point of his finger, and at other times it may be requisite (as in using the stomach-tube in those who have swallowed soporific or intoxicating poisons) to have a gag (fig. 362), as it is technically named—that is, a piece of wood, placed between the teeth, with a hole in the centre, through which the tube is inserted, — which prevents the individual offering any obstruction to the point of the instrument, or closing his jaws upon it. When the larynx is to be reached, it will be advisable that the patient should project the tongue so as to bring the epiglottis forward.

Wounds of the neck must in general be treated according to the
ordinary principles of surgery, and although it is often the custom to allude to such cases as requiring peculiar modes of practice, I cannot perceive any difference that may be necessary further than what a knowledge of anatomy and physiology might indicate. Those most commonly met with in civil practice are in individuals who attempt suicide with a razor or other sharp weapon. In such cases, supposing that the escape of blood has not caused immediate death, the first object which the surgeon has to attend to is to prevent further effusion should such action be found necessary: he must cleanse the wound with a sponge and warm water, and secure the bleeding vessels as he would in other parts of the body; next he should bring the edges together, and retain them by stitches, taking care to keep the patient's head forwards, so as to cause the surfaces to approximate. Whether the trachea, larynx, or pharynx be opened, I can see no material difference in the practice, in so far as the above directions go: perhaps the whole wound may unite by the first intention, or possibly air may pass through part of it, or fluids taken by the mouth may escape; in none of these events can complete union occur at once; but in such cases the open points may heal by granulation. In the air-passages it will be the duty of the practitioner to watch that inflammation, or that matters from the pharynx or gullet, do not interfere with respiration; in those leading to the stomach it will be necessary to see that sufficient nourishment is allowed to pass downwards, and possibly a small tube, leading from the mouth or from the wound to that part of the gullet below the injury, may be required for a time.

Tumours in the neck are of frequent occurrence, and operations for their removal usually require more caution and surgical skill than similar proceedings in other parts of the body. The most common of all swellings in this situation is that connected with the thyroid gland, so well known under the term of Bronchocele, Goitre (fig. 363), Derbyshire Neck, &c. &c.: but such an affection is seldom, among surgeons of the present day, considered a fit case for interference with the knife. Although Gooch, Desault, Hedenus, and others, dissected out such tumours, and Klein of Stuttgard wrote so familiarly (flippantly, I should say) about such operations, few leading surgeons now countenance such proceedings; nor, indeed, excepting in cases where the tumour attains a large size, does it appear to give any inconvenience saving that arising from its unseemly appearance. Anatomical examinations of such enlargements display the thyroid arteries, one, two, three, or all of them prodigiously increased in size, the carotids in close contact with the mass, which itself is so intimately connected with the important parts at the root of the neck, trachea, and oesophagus, as to forbid any attempt upon the entire growth by
means of incisions. On one occasion, in a case where the affection produced more than usual annoyance, I witnessed an attempt by Mr. Liston to remove a portion of this gland, but the operator was speedily obliged to desist in consequence of profuse hemorrhage: a needle was thrust across the swelling (which was chiefly in the middle or the isthmus), and a stout double thread was tied tightly round the most prominent part, by which the blood was restrained; a slough followed, and the patient was relieved of a troublesome, tickling cough, which had resisted all other means of cure. Roux, after expending more than an hour in removing a portion of this gland about the size of an orange, and applying forty-seven ligatures, lost his patient fifty-six hours afterwards.

In some young subjects the frequent use of leeches and of iodine may check this disease, or actually cause its disappearance. I have seen examples of the kind; but such cases are few in comparison with the numerous instances where these and other means fail. Ligature of the enlarged arteries has occasionally been performed; but the success does not seem to have been such as to induce frequent repetition of the practice: Sir William Blizzard put it into execution, Walther, Coates, and others, have tried its efficacy, and Professor Chelius, of Heidelberg, has related two cases in which deligation of the superior thyroid was successful. Although the disease abounds in Britain, I have seen no interference with it (excepting in the case above referred to) otherwise than by the ordinary means which are supposed to have a restraining effect on the growth of tumours, and in these, as may be gathered from my general remarks on such matters in the chapter devoted to the subject, I have but little confidence. In early disease, particularly in the young, I should be inclined to persist in their use, as the disease is not such as should be at once attacked with the knife, nor indeed should any attempt of the kind ever be made excepting under peculiar and urgent symptoms.

An example of tumour of the thyroid came under my care at our hospital, which seemed to me worthy of further investigation than a mere external examination would permit. The swelling, which was on the left side, in a female aged forty, had many of the symptoms of a cyst, especially in this respect, that by pressure with the finger and thumb the substance within could be displaced as if it were so much atheromatous material contained in a bag. Under this impression I imagined that the contents might be turned out, and that a portion at all events of the cyst might be dissected away. Having, however, no firm faith in this diagnosis, I resolved to proceed cautiously with a sort of exploring incision, and accordingly used the knife at first, to a very limited extent, on the surface. Ere the sac was reached the bleeding was sufficient to convince me that excision was out of the question. A few additional applications of the knife showed that there was great vascularity on the outside, and as soon as the sac was punctured the blood gushed freely from the inside also. In a wound little more than an inch long I had to apply four ligatures, and was
fain to stop with what had been done. The interior of the sac seemed filled with a sort of cauliflower excrescence, which bled freely on being touched, and I afterwards perceived through the orifice in the sac, which was kept open for some days, that the kneading process with the fingers, above alluded to, caused the blood to ooz out very copiously. Cysts of this kind in the thyroid body are not often met with, at all events they are rarely touched by the surgeon.

Another instance has occurred to me in private practice, which looked more favourable for an operation. There was a tumour prominent and well defined, about the size of a large orange, on the left side of the neck, in the site of the lateral lobe of the thyroid. Fluctuation was most distinct, and the cyst and skin over it seemed so thin that I was in hope of being able to remove the whole or greater part of the bag without much trouble. On opening the tumour with an incision about an inch long, the serum with which it was filled flowed out at once, and I was enabled to pass my finger into the interior. I then found that the cyst was equally thin all round, about the thickness of the dura mater, and that it lay so closely in contact with the common carotid artery that the vessel felt as if it were not covered by more than its sheath. It was my intention to try to remove the cyst by enlarging the external wound, and partly dissecting, partly tearing it from the surrounding tissues, but to my astonishment the interior filled again with great rapidity, with florid-coloured blood, which, on being removed, was so speedily followed by more, that I deemed it unwise to continue the operation. A ligation was applied to a superficial vessel, which bled freely. The gap was in part filled with lint, but although blood oozed away in considerable quantity for some time after, there seemed no need for interference. Inflammation and suppuration ensued, and after a feverish state, resulting from these conditions, there seemed little peculiar in the case, excepting a most offensive smell from the wound or sinus, which still had a free opening on the surface. About six weeks after the operation a considerable slough came from the interior, which, on examination, was like a large portion of the cyst. The wound speedily healed, and the lady has now been well for years, and highly pleased with the result, as the operation was desired for the sake of personal appearance.

I have now met with a number of such cases, and it is not unusual to apply the word "hydrocele" to them. Occasionally they have been treated like hydrocele of the tunica vaginalis, by tapping and injecting iodine. I have seen an instance where this plan was followed by coagulation of the fluid exuded subsequently to the injection: this fluid, I have no doubt from the experience above quoted, was chiefly blood. Great irritation in the sac was set up, and much fever ensued; suppuration in the sac erysipelatous inflammation followed, and it became needful to lay the sac, freely open, to permit the escape of pus, fibrin, and clots of blood. The patient had a narrow escape from death. This case, with others of a like kind which I have treated, makes me chary of interfering by any other method than simple tapping. A
TUMOURS IN THE NECK.

573

seton might be used, but I should be as apprehensive of evil from it as from injections.

Fatty growths are of very frequent occurrence in the subcutaneous cellular tissue in the neck, but need no special comment here.

Aneurism by anastomosis in its usual form is by no means uncommon. The disease may be cutaneous, subcutaneous, large or small, as in other localities, and the mode of treatment must be that which is generally followed elsewhere. One of the most remarkable instances of this disease which I have ever met with was in this locality. There were numerous tumours of many years' growth in a middle-aged woman, and her appearance is well represented in Fig. 364.

Emboldened by experience, I thought of removing the most conspicuous of these growths by the knife, and succeeded in so doing without any remarkable occurrence. The various tumours thus removed had numerous phlebolites within them—one of the few instances of the sort wherein I have noticed such deposits in aneurism by anastomosis.

The most frequent kinds of tumours are, probably, connected with the lymphatic glands. These may form in any part of the neck, may be superficial or deep, not larger than a garden pea or equal in size to the patient's head; they may be strumous, fibrous, of the simple sarcomatous character (perhaps the most common of all), or present the features of scirrhus, medullary sarcoma, or other species usually enumerated in classifications of such diseases. Although gottre is frequently seen in those who possess the scrofulous diathesis, the latter disease but rarely shows its peculiar characters in the thyroid gland; and the parotid, submaxillary, and sublingual, I feel assured are rarely the seat of actual enlargement of any kind. Thirty or forty years ago it was more the custom to speak of tumours of the parotid than at present, and similar language is still occasionally used in the medical journals, but for my own part I cannot say that I have met with a single unequivocal case of the kind. I have seen and removed many swellings in the seat of the parotid, but have invariably noticed that these were, to all appearance, developed in a lymphatic gland, or in tissue.
different from the parotid. When such tumours were small, the parotid was slightly compressed, or perhaps turned aside; and when large, most of it had disappeared.

The diagnosis of tumours in the neck is often difficult, and the most skilful surgeon will occasionally be uncertain as to the propriety of attempting their removal with the knife. Aneurisms in the neck are seldom difficult to detect; Allan Burns and Sir Astley Cooper long ago pointed out the possibility of this disease being supposed to be in the carotid or subclavian vessels at the root of the neck, when, in reality, in the innominate or arch of the aorta: but elsewhere their diagnosis is usually very clear. I have seen many tumours and large deep-seated abscesses above the clavicle, in the course of the subclavian arteries, which in many respects, and on a slight examination, resembled aneurism of these vessels. Upon the whole, however, a mistake can scarcely occur in such cases if anything like reasonable care be taken in investigating their nature.

Such a tumour as that represented in this sketch (fig. 365) is of common occurrence. The well-defined circumference, the prominence of the mass, its superficial site, and the healthy aspect and natural position of all the parts in the neighbourhood, clearly show the absence of all objection to an operation. In removing such a tumour as this, through a single perpendicular or by a crucial incision, the bleeding may be considerable from a number of small arteries,—branches of the external carotid or temporal, but in all probability ere the mass is fairly separated, by the cautious dissection required, where it lies on or in the parotid, there will not be a single ligature required. There may, however, be several necessary, and should the knife be carried rashly round the back or under part of the tumour, one or other of the transverse facial arteries might be cut so near to the trunk of the internal maxillary or temporal, that it might be troublesome to apply ligatures. There is a risk, too, of dividing the common trunk above named, when the trouble would be still greater. Where there is danger of such an occurrence, there is also risk that the portio dura may be divided, in which event the features will become considerably distorted, and the mouth will be drawn in a marked manner towards the oppo-
site side. Beyond the paralysis of the side of the face on which the nerve has been divided, there is no greater evil, but it is an unfortunate occurrence, and greatly to be avoided, if it be in the surgeon's power. I have repeatedly, in removing tumours from this locality, seen the portion dura lying immediately behind the course of the knife, and have had reason to congratulate myself on the cautious use to which it has been put. Indeed, in latter years I have in this locality more than in any other followed a favourite practice of my own, that of partly pulling partly squeezing out the mass, using the scalpel only where absolutely needful.

The tumour represented in figure 365 may be considered of an average size, or perhaps a little larger. Often the surgeon interferes when they are much smaller, and in some of these instances the removal is more difficult than when the mass is larger. As has already been stated, small tumours in this locality are sometimes remarkably firm in texture, so that their hardness is considerable. As such growths increase in size, they have a tendency to soften, and I have seen this so remarkably exemplified in various instances, that at several points where the softening was greatest it was difficult to draw a distinction between the condition and some forms of medullary sarcoma. Usually, however, such growths are of a non-malignant character, even when there is softening.

In my own personal experience I have met with an average number (if not a few more) of such cases, as they fall to the lot of hospital surgeons. Two years ago I saw more, probably, than may be usually met with by one man in the space of twelve months. Besides several small tumours and one of great size, I saw four where the growths were all of considerable magnitude and nearly of a size. Two of them were as closely of the same size as possible, but the history was importantly different, and a careful examination detected some remarkable features of distinction, which I shall here endeavour to explain. At a first and casual glance the two cases, represented in figures 366 and 367, appear much the same, but the physical features and a part of the history of each will show most important distinctions. Figure 366 is taken from a cast from a tumour which had attained
the size represented in less than two years. The mass was hard and elastic, and seemed to involve all the important parts on that side of the neck. It was impossible to define exactly the distinction between it and the tissues on its circumference, and it could not be moved without moving the whole head at the same time. It seemed so thoroughly amalgamated with the neighbouring tissues that it was actually more in them than on them. In figure 367 the lateral projection was equally great; but here the growth had been thirty years in progress, and even at this time its circumference was easily distinguishable; the skin over it was not in any special way attached to the mass, and the tumour itself could be distinctly moved upon the subjacent tissues. In the instance of figure 366, the whole mass seemed in the process of rapid development, and although the constitution had not yet suffered, the disease had not only most of the characteristics of malignancy, but, above all, it was evidently so attached that an operation for its removal was, in my opinion, out of the question, although the poor man had come nearly three hundred miles for the purpose of having one performed. This patient died not long after I saw him from rapid and great enlargement of the growth. In the case represented by figure 367 some points of the tumour had accidentally become inflamed, and the tissues had been a little softened near the surface, but the bulk of the growth was hard and elastic, and was evidently of the same character as had been present for thirty years. This age of a growth is one of the surest tests against malignancy, and although, even at a distant period, malignant action might come on, it is of very unlikely occurrence. The whole history of this case, the slow growth of the tumour, its clear distinction from the surrounding or rather subjacent tissues, and the practicability of its removal without the risk of injury to important parts, all combined to lead me to an operation, which was accordingly performed without serious injury to the contiguous parts. Unfortunately, however, erysipelas ensued in a few days, and the patient, a stout able-bodied man, about forty-six years of age, died on the fourteenth day afterwards.
The bulk of the tumour presented the usual fibrous aspect of such growths, and where inflammation had been present, the substance was softened so as to give an appearance not unlike medullary sarcoma. The particulars of this case were published in The Lancet, 22nd December, 1849.

Some years ago, during a temporary visit to Scotland, I was consulted about another case in most respects similar to the instance above detailed. The tumour was smaller, however, and had been remarked for about eight years only. The skin was quite moveable over it, the mass itself could be readily moved upon the subjacent parts, the patient was young and healthy, and an operation was clearly the proper step. The patient had my opinion to this effect, and I learnt soon after that she had been placed under the able hands of Mr. Synge, of Edinburgh, who had successfully relieved her of the cause of her distress. Within a few weeks after I had seen this case I operated on a tumour similarly situated, on a patient of Mr. Wood, of Roehdall, of equal magnitude. The growth had been of twenty years' date, and was, perhaps, a little more firmly fixed than either of the two last referred to. There was nothing, excepting bulk, to contra-indicate an operation. Here, however, the portio dura had been involved in the mass, for, notwithstanding my anxiety to avoid it, it was cut, and paralysis of that side of the face was the effect. In all other respects the result of the operation was most satisfactory, and I saw this patient years after the operation in the enjoyment of perfect health.

Recent experience has brought under my observation several still more remarkable examples of tumours in the neck. In the spring of 1869 I was consulted by a lady with a growth on the left side of the neck, nearly half the size of her head. Seven years before a small tumour had been removed from the vicinity of the parotid, but a new growth rapidly came after cicatrization. Four years after she was advised by surgeons of the greatest note to leave it alone. I fancied that, from slight indications of mobility, it might be removed without fatal injury to the surroundings, and with the concurrence of Mr. Cesar Hawkins performed an operation for its removal, during which all great dangers were avoided, and a most successful result ensued. The preparation is now in the Museum of the College of Surgeons. During the operation some firm fibrous adhesions to the lower jaw had to be separated, and a well-formed bicuspid tooth was found within the mass at this part. There was no reason to suppose that this tumour had been originally connected with the jaw, and I am not aware that the presence of a tooth in such or similar growths has ever been noticed before.

I looked upon the above case as one of the most remarkable I had ever seen, and as requiring one of the most difficult operations which had ever fallen to my lot. It was, therefore, not without wonder that I met within a fortnight after a case even more formidable. This figure (368), will give some idea of its appearance. The growth was of thirteen years' date. For peculiar reasons the patient, an officer on service in India, had put off the chance of an operation from time to
time, until at last a fatal termination seemed likely to occur from repeated bleedings from large vessels in the skin, which burst into ulcers

*Fig. 368.*

resulting from over-distension. The patient had come home from India with the intention of undergoing an operation; and accordingly, with the sanction of Mr. Cæsar Hawkins, Mr. Prescott Hewett, and Mr. George Pollock, I removed the mass. The bleeding from the vessels on the surface was copious, but no deep vessel of magnitude was involved, nor did any nerve seem implicated. The sterno-mastoid was spread considerably over the mass, and had to be divided. The operation, which lasted only a few minutes, thanks to the able assistance of Messrs. Hewett, Pollock, Henry Smith, and F. Mason, actually seemed less severe than that referred to immediately preceding, yet the patient sank within eighteen hours, having never thoroughly rallied. The tumour weighed nine pounds and a half. It was chiefly fibro-granular, and is now in the Museum of the College of Surgeons. A most interesting case similar to this was published by Professor Spence, of Edinburgh, in the Dublin Quarterly Journal of Medical Science for November, 1863. The tumour weighed more than seven pounds, and the operation for its removal was eminently successful.

The difficulties of deciding a question as to the removal of certain tumours by incision can scarcely be appreciated, unless by those who have the cases before them. The mobility of such growths I consider the most valuable criterion of all; and if it were evident that the part slid freely over the subjacent textures, I should not hesitate about
TUMOURS IN THE NECK.

579

using the knife, whatever might be the bulk of the disease, provided there was no other circumstance to contra-indicate such a proceeding; but if, on the other hand, the tumour seemed fixed to the neighbouring parts, if its limits were not clearly defined, if an attempt to move it caused pain, I should not readily be induced to use the knife, however small the mass might be. When the tumour is under the platysma, or superficial fascia, in or under the parotid, it is likely to present most of the latter objectionable characters; yet a careful examination with the finger may probably lead the surgeon to perceive that it is only bound down by the textures over it, but not inseparably connected with those in the vicinity. If two or more lymphatic glands are affected at the same time, it will be well to watch the progress of the case before deciding to attempt removal; for if these organs be predisposed to disease, many of them may speedily assume the same condition, and in such examples no operation is justifiable. Many years ago I attended a boy with a tumour about the size of a small orange, in the upper part of the neck, which it was proposed to remove; but as it seemed fixed, and the case appeared otherwise unfavourable for such practice, I did not interfere; within a few months small glandular swellings could be detected on the opposite side; these gradually increased, and the patient ultimately died from starvation and suffocation, occasioned by an enormous swelling on each side of the throat, which impeded both deglutition and respiration. Dissection showed that most of the lymphatic glands in this situation were more or less involved, and that the pharynx was encompassed behind and at the sides with the diseased mass, which, in addition, surrounded the main vessels in such a manner, that I had reason to congratulate myself on my non-interference. In museums there are generally plenty of specimens of similar cases, where probably the common carotid, internal jugular, and par vagum, are seen passing through the centre of the enlargement. I know of one instance where a surgeon, in attempting to remove such a tumour, cut all these parts across, and secured them in one ligature; the result (death) will not be difficult to conjecture.

I have seen a surgeon attempt the removal of a fixed tumour not larger than a walnut, situated in front of the transverse processes of the vertebrae at the root of the neck; but he durst not proceed, for, after detaching the integument over it, the disease remained as fixed as ever, and seemed so connected with the nerves and other textures, that he wisely saw the propriety of desisting. I have known something of a like kind occur under the upper end of the sterno-mastoid, when the surgeon should not have interfered. Mr. Luke, of the London Hospital, showed me a mass the size of the fist, which he successfully removed from the situation of the parotid; it had been deep, and firmly fixed, and a vessel was pointed out as the external carotid, a part of which had been taken away at the same time; yet the bleeding was not so great as might have been expected, and the case did well. Mr. Carmichael, in dissecting out a large tumour from this locality, divided an artery which was supposed to have been the external carotid; and here also the result was favourable, although the hemorrhage was most
copious, and was commanded with difficulty. Mr. Crosse has related a case where, in the removal of a small tumour from behind the angle of the jaw, a vessel was cut from which the hemorrhage was so profuse that a ligature was placed on the common carotid; even this did not restrain the flow of blood, and the patient perished.

In all operations like those under consideration, the general rule of planning the incisions in such a way as to leave the smallest possible amount of scar afterwards, should be carefully kept in view; the operator should not, however, confine his movements to a narrow space, by limiting his external incisions, and should bear in mind that the patient's safety is of more consequence than avoiding a small additional extent of superficial wound; therefore I recommend that in removing tumours, or exposing large arteries in this locality, the external aperture should be sufficiently free to permit as favourable an examination of the parts about to be cut, as the circumstances otherwise will admit of.

In such an instance as this, for example (fig. 369), I had difficulty in deciding what line of incision to make. I fancied that one straight across would suit my purpose best, and leave the smallest perceptible scar. I accordingly made it, and had the satisfaction of turning the tumour out with great facility, and with ultimate success. The growth had been of sixteen years' duration, and though in a different locality, resembled in most respects that represented on page 576.
CHAPTER IX.

DISEASES OF, AND OPERATIONS ON, THE JAWS.

The jaws and other bones of the face are subject to caries and necrosis. Perhaps caries is most frequently seen in the upper maxilla and contiguous bones,—necrosis oftener in the lower jaw; and the surgeon may occasionally show both skill and dexterity in removing these sources of irritation. Such proceedings are usually very simple, although sometimes the sequestrum in the lower jaw is so large as to cause the operation for its extraction to be almost as formidable as for the excision of a portion of the bone for tumour. If possible, the diseased or dead portions should be removed through the mouth; but sometimes, especially in the lower jaw, free external incisions are absolutely necessary. I have seen the whole of one side of this bone, from the mental foramen to its neck, removed in a state of necrosis; and I have frequently extracted very considerable portions of its base, either through the mouth, or through an external incision along the lower margin of the face, being at the same time obliged to divide the facial artery. In the twenty-first volume of The Transactions of the Medical and Chirurgical Society, a case is related by Mr. Perry where he extracted the whole of the inferior maxilla for necrosis: the bone was taken away piecemeal on different occasions, and the incisions were made on the outside; and in The Lancet for July, 1857, is a case of a similar kind, in which about one-half of the bone was first removed by Mr. Solly at St. Thomas's, and the remainder many months afterwards by Mr. Thomas Wakley at the Royal Free Hospital. The swelling in such cases is usually very alarming to the inexperienced, but it soon subsides after extraction. In operations for the removal of dead portions of bone in this locality, I have found stout forceps of this shape (fig. 370) of great service, whether in removing portions through the mouth or through wounds on the external surface. Of late years I have improved upon these, as I fancy, by having the blades stronger, shorter, and so made at the ends as to ensure a firmer hold of the bone and a firmer grasp in the surgeon's hand. Fig. 371 shows the difference
in shape; and I call attention specially to the grasping blades, where it will be seen that the teeth slope backwards, besides being rougher

**Fig. 371.**

than usual, and that although open they lie nearly parallel with each other, so that a greater extent of surface will elapse the sequestrum.

Abscesses (gumboils) frequently form in the vicinity of the alveoli, which for a time usually occasion considerable pain and swelling. I deem it good practice in these instances to make an early and rather free incision, as, besides the relief thus given, there is less chance of matter getting into contact with bone, in which event caries is not unlikely to be the result. In some of these cases the abscess bursts on the cheek or chin, and often sinuses remain seemingly incurable for years after. A piece of dead bone will probably be the cause of this protracted suffering, or, what is by no means uncommon, there may be a tooth or bare fang, near which the abscess may have originally formed. In such a case extraction of the tooth or fang is essential, although possibly dead bone may have to be extracted also.

Tumours of various kinds form in connexion with the mouth and jaws. They may be on the gums or in the bones; but when large, it rarely is otherwise than that both are more or less affected.

The term epulis is generally used to denote tumours of the gums: such growths are invariably of a sarcomatous character,—in one case the mass is soft and spongy, in another of a more solid kind,—probably medullary, and in rarer instances a melanotic deposit occurs. At first there is, perhaps, only a small spot on the outer or inner side of the gums; but gradually, unless the surgeon interferes, the neighbouring parts are involved, until at last the disease becomes extensive—implicating perhaps the whole alveolar processes in the vicinity, and even some of the more solid textures beyond.

The hard parts of the jaws are in some instances primarily affected: here the swelling may consist of solid bone—a kind of exostosis, or, it may be an osseous cyst containing a glairy or a serous fluid,—in one example it may be a sort of fibrous mass, or it may be a mixture of spicule or laminae of bone, with the interstices filled up with a sarcomatous substance—the latter being in one case of a semi-cartilaginous character, and in another of a soft, pulpy, medullary nature. At first the gum will not be affected; as the growth increases, however, particularly if it is of a soft character, the teeth become loose, and fall out, the gums swell and ulcerate, and then an ill-conditioned sore is formed, from which there is a most offensive discharge.

In the lower jaw one or other of these forms of disease is far from being uncommon. In the instance of epulis, however benign the
growth may appear at first, the surgeon should not hesitate to propose its removal; for although examples will be occasionally met with where the unhealthy action seems to cease, the greater number go on from bad to worse, and a more serious proceeding is ultimately necessary than would have been required at first. Once I saw a tumour of this kind, about the size of a walnut, connected with the gum within the incisor teeth of the lower jaw: the patient had nearly gone her full time with child, and I did not, therefore, advise its immediate removal, although this might have been very readily accomplished, as it was attached only by a small neck: in the course of a few weeks after she rubbed it off with the point of the tongue, and was never further troubled. I have seen a case analogous to this in the upper jaw, immediately behind the two principal incisors. Here the neck of the tumour was so slender that I broke it with my fingers and so set the growth free. Cases of epulis seldom terminate so favourably, however, and some energetic means (more so, even, than the female tongue) must be resorted to. The pain and uncertainty of caustics are, in my opinion, sufficient objections to such remedies, unless when the disease is very limited: in general it will be best to remove it by the scissors or knife; and should the textures around be in a suspicious condition, it will be wise to remove them too: the cutting forceps may be required if the alveoli are implicated, and here the shape indicated in this figure (372) will be found of great utility, or such an instrument as this (373) will answer admirably to cut the alveoli across.

If the swelling is more in the body of the bone, it will not be so easily managed. Supposing it to be an osseous cyst, and that the surgeon has ascertained this by touch, or with an exploring needle, which may be advantageously used in some of these cases, possibly by making a free opening between the gum and the cheek, thus allowing the fluid to escape, then stuffing the cavity with lint, and treating it as we should an abscess, the walls may gradually contract and consolidate in a firm cicatrix. Perhaps in some such instances a seton passed across the cavity might be of equal avail.

Fig. 372.  Fig. 373.
Such a case may, however, not go on so satisfactorily. A loose spongy mass may form in the place, or possibly it may be found that the bone around is in a condition in which a cure cannot reasonably be expected from such treatment. In other instances, the surgeon may see from an early period that a more formidable proceeding will be requisite. Now, the only course will probably be to remove a portion of the jaw throughout its whole thickness; but if this can be avoided,—if the base of the bone can be preserved, an attempt should be made to do so. I once succeeded in this object in the following manner:—The patient, who had a malignant-looking affection of the gums and alveolar processes in the mental portion of the maxilla, was seated on a firm chair, and an incision was made directly downwards from each angle of the mouth, as low as the base of the bone; the lip and soft parts between these wounds were then dissected towards the neck; next the anterior molar tooth was extracted on each side, and a slight note made with the saw, such as is delineated in figure 376; the same instrument was then applied in a horizontal direction midway between the alveoli and the base, and, a note being made, the cutting pliers, represented in figure 372, completed the separation. The external wounds were then brought together by the twisted and interrupted sutures, a piece of lint was laid along the cut surface of the bone; union occurred on the face, granulation and cicatrization within, and a perfect cure was the result. Figure 374 exhibits the part which was removed. This operation was done in the Royal Infirmary of Edinburgh, more than thirty years ago, and I heard of the patient long after, when he still continued well.

The great advantage of such a proceeding is, that less deformity results than when the entire depth of the chin is cut away: the sides of the bone are prevented from falling inwards, as they invariably do in the other case: the jaw, in short, was left as if all the front teeth had dropped out,—just as may be seen in aged persons,—and there was sufficient foundation to affix a saddle with false teeth, had the patient chosen, whereby the lip would have been supported in its natural position. I am not aware that such a proceeding has been much followed in this country excepting as regards a small extent of the alveolar ridge, although similar proceedings have occasionally been adopted in America. I have been induced to allude to this case, both because such a mode of operating is less generally known than by perpendicular division of the entire thickness of the bone, and also from supposing, from what I have myself seen, that it may be advantageously resorted to in some instances where more severe measures are contemplated. The steps above described would be more troublesome towards the back part of the alveolar ridge, yet by judicious
incisions externally they might be accomplished in a satisfactory manner. In the present day I imagine that I could improve most importantly on this proceeding, for an amount of bone equal to this, and even greater, could readily be removed through the mouth by means chiefly of the semicircular forceps (fig. 372), without the saw and without the incision on the chin or face.

In certain cases it is absolutely necessary to remove the base as well as the alveoli, and supposing the disease to be in the mental portion of the bone, the proceeding may be effected thus:—After the first incisions have been made as above directed, the flaps should be dissected from the inferior margin, and then a notch with the saw should be made in a perpendicular direction on the anterior surface of the bone: next, the straight-cutting forceps (fig. 375, or 380) should be applied,—one blade within the inner table, the other in the groove,—and the bone divided: then the soft parts within—the digastric, part of the mylo-hyoid, the genio-hyoid, genio-hyoglossus on each side, and mucous membrane—being cut across, the separation will be effected, and the wound may be dressed as already described, or as circumstances may indicate. To make room for the blade of the forceps being applied within, it may be well to run the knife up at that part so as to clear a space; but unless the forceps be large and coarse, this step need not always be attended to. The bleeding will not be at all troublesome; possibly each labial artery may require a ligature; but the twisted suture, which should always be used at this part of the wound, will usually compress them. Even here I should at present follow a different plan as regards the external incision, for by cutting freely along the base of the bone a sufficient opening could be made through which a narrow saw (fig. 376) could be applied, as also the forceps, with one or both of which the tumour would be so loosened that it could, with a few additional touches of the knife, be removed either through the wound or by the mouth.

Instead of dividing the bone, as above recommended, a chain-saw has been used for the purpose by some operators. The instrument is delineated in Dr. Jeffray’s work on the Excision of Carious Joints; but, notwithstanding the success with which it has been used by such a high authority as Mr. Cusack, I give decided preference to a small dovetail saw (p. 7), or to such an one as is here represented (fig. 377). A similar instrument has been advantageously used by Dr. Warren in
many of his operations; and, to one accustomed to cut with such tools, there is no difficulty in notching the bone in the manner directed. The handle is about three inches and a half long, the blade the same,

![Fig. 377.](image)

and may be a quarter, a half, or a whole inch in depth. As the plate is purposely very thin, to permit the teeth being twisted outwards, as in a properly-set saw, a back is required to keep all firm. When the blade is deep in the bone there is less need for the back, and it is not unusual to make this part moveable as here represented below, so that when it comes in contact with the bone it may be raised to let the saw deeper. The instrument is light and handy, and I have often used it for excision of the knee in preference to all others. This figure (378) represents a small saw specially for jaw operation, with the moveable back raised from the blade.

![Fig. 378.](image)

It has been remarked, that when the attachments of the tongue to the chin have been divided, the organ has been suddenly drawn back so as to endanger suffocation: indeed it is stated that Magendie lost a patient in this way, and Lallemand is said to have performed tracheotomy in one of his cases: the point should, therefore, be kept steady by an assistant, who can use his fingers, forceps, or hooks, as may be required; or, what answers best of all, a thread should be passed through the apex, and a loop being cast, the part can thus be kept in a proper position. This appears an additional severity; but it is perhaps a wise precaution, particularly in operations where larger portions of the bone are removed. In modern days, when chloroform is, or ought to be invariably used on these occasions, there need be little ceremony in dealing with the tongue as regards seeming roughness of handling; but to say the truth, I doubt if there is such danger from retraction of the tongue as was originally supposed.

In dressing the wound within the mouth, care should be taken, by inserting a due quantity of lint, to keep the sides of the bone from falling inwards: the pterygoids and the remaining portions of the mylo-hyoids will conduce to this effect, the disadvantage of which is, that besides causing the deficiency at the lower part of the face to be more conspicuous, it removes the teeth from the line of those above.
Mr. Nasmyth, of Edinburgh, contrived a simple and ingenious instru-
ment to obviate this change in position: it consisted of a double silver
case to contain the upper molars and those below, which was made to
fit on previous to the operation, when the jaws were nearly closed.
This machine was used by Mr. Liston on several of his patients, and
answered the desired object, and I have subsequently seen much
advantage from it in my own practice. It is, perhaps, however, best
adapted, or at all events, most necessary, in instances where the whole
of one side of the maxilla has been removed, such as in ease repre-
sented by 383, afterwards referred to, where I found such an apparatus
of great service.

The operation for removing a large portion of the lower jaw may be
accomplished in this manner:—The patient being seated as in the
preceding operations, or most probably recumbent, under chloroform,
supposing the portion of bone about to be removed to extend from the
angle near to the symphysis, the knife should be carried down the lip
from about its centre to the lower margin of the chin, when it should
be run along the base of the bone as far back as the angle, and then
slightly turned up along the posterior border; the flap thus marked
out should be turned upwards by dissecting it from the tumour: next
an incisor tooth should be extracted,—perhaps the last molar also,—
and the dovetail saw (fig. 7), or one of those represented on the pre-
ceding pages, should be used to effect a fissure in the bone in front
and behind the disease, when the forceps should be applied as already
directed, and the separation completed by dividing the attachments of
the soft parts within, viz., the mylo-hyoid, part of the internal ptery-
goid, perhaps, and the mucous membrane.

In the incision below the jaw the facial artery must be cut: the
knife, however, may be so lightly carried over this part, that it need
not be divided until the flap is being raised, when it can be secured
with a ligature, or commanded with the finger of an assistant: in the
latter case, a thread must be applied ere the wound is closed. It is
not likely that any other vessel will prove troublesome. When the
knife is swept boldly along the base of the bone, this artery is sure to
be divided, and occasionally, as I have seen, the gush of blood is very
copious: yet even in such a case I have found at the end of the opera-
tion that a very diminutive stream continued: whether large or small,
a ligature should invariably be applied; for if it is not, bleeding is
almost certain to ensue when the patient gets warm in bed and
recovers from the immediate shock of the operation. It will now be
well to apply a ligature to the upper end of the vessel, as I have known
secondary hemorrhage from this quarter ten days after such an opera-
tion as that described.

A flap might be made by passing the knife in a horizontal direction
parallel with the teeth from the angle of the mouth to a little above
that of the jaw, and another downwards in the course of the symph-
ysis, but the external wound might thus be too small, and the cicatrix
would be more conspicuous than that following the incision above
advised. In latter years I have been much convinced of the wisdom
of not cutting the lip at all in such operations. A wound of the prolabium can never be altogether concealed, and as a lunated incision can be stopped short of this margin, whilst the subsequent steps of the operation can be performed with almost equal facility, I strongly recommend conservation as regards the labial orifice.

Sometimes disease is so situated that the angle of the bone, with a considerable portion—perhaps the whole—of the ascending ramus has to be removed. If a small part only of the latter is affected, the incisions already described—at all events carrying that over the posterior border a little higher—will permit the application of the saw and forceps. The bone in this situation is somewhat harder than in front, and from this circumstance, as also from its position, there will be greater difficulty in using the forceps depicted on p. 585. The shape indicated in these figures, 379 and 380, will perhaps be more serviceable at this part. When the jaw is interfered with here, the proximity of the external carotid must be remembered.

If the disease extends so high as to approach the neck of the bone, it will probably be best to disarticulate. The tumour may be small or large, may involve little in front of the angle, include the whole of the body on that side, or possibly even the chin and a considerable extent further round. Supposing it to be of a size such as here represented (fig. 381), the proceedings may be conducted in the following manner:—The patient being seated as for the other operations, the knife should be carried from the lip downwards, backwards, and upwards, as indicated by the dotted line on the drawing: the facial artery being doubly secured in the manner already indicated, the bone must be divided in front with saw and forceps, as also described in a preceding page, when the mass must be drawn outwards (to one side), so as to permit the point of the knife being carried along its inner
surface: the anterior attachments of the tongue (supposing division of
the bone to have been effected further round than the symphysis), the
mylo-hyoid, the mucous membrane, the internal pterygoid, the mas-
seter, the temporal, the external pterygoid, and lastly; the lateral liga-
ments and synovial capsule, should all be divided successively, and so
the separation will be accomplished.

If the tumour is small, in all likelihood the articulation may be
in a natural condition: but under such circumstances, as the mass will
probably be tolerably firm, it can be advantageously used as a lever,
whereby the action of the temporal muscle may be opposed, the coro-
loid process drawn downwards, and the condyle, in a manner, twisted
out, after a slight application of the knife to such ligamentous fibres as
are thrown on the stretch. In many instances, in disarticulating on
the living body a solid bony tumour, I have found that the condyle
actually separated from the periosteum on its inner side, and this part
of the proceeding was therefore accomplished with great facility. If,
on the other hand, the tumour is larger, the mouth may have been
kept open for some time before, and the temporal muscle will there-
fore be easily reached, while the stretched state of the joint may pos-
sibly permit the separation of the condyle to be readily effected. In
such a case the lever force is not so much to be trusted to, as the
growth will probably be so soft as to tear across: this I have seen
happen a little below the neck of the bone, where the large mass
separated, and the condyle with the coronoid process, and some
remaining portions of disease, were then dissected away.

Sometimes the cutting forceps have been used on the coronoid pro-
cess and neck of the bone, and the parts above have been left. I
should in general, however, prefer removing them, as being a simpler
proceeding, and not in any way causing either additional pain or
danger to the patient. Once authority has recommended that the joint
should be opened in front; another that the knife should be entered
behind: for my own part, I should begin here at any point which
seemed most convenient. The main source of apprehension regarding
this step of the operation has been the proximity of the internal maxil-
lar artery; but there need be far less dread on this score than many
have imagined. If the point of the knife is kept close upon the bone,
the vessel can scarcely be touched; and should it actually be divided,
the bleeding can be easily restrained with the finger until a ligature
is cast around it. When the condyle and neck are separated, the
artery lies in a large wound, whose depth is not so great as to prevent
the orifice being seized with forceps, or transfixed with a tenaculum;
but if the operator thrusts the knife deep behind the ascending ramus,
so as to wound this vessel, the root of the temporal, or perhaps even
the external carotid itself, and is afterwards awkward and slow in
effecting the removal of the bone, the bleeding might be very copious.
To avoid such a danger, it may probably be best to proceed from
before backwards; and as in this way the temporal muscle should be
separated from the coronoid process, there will then be less difficulty
in effecting that process of twisting which I have recommended.
Besides the external maxillary artery, which must of necessity be wounded, the transverse facial branches must be divided by the vertical part of the incision over the ramus: these will bleed profusely for a minute or two, but probably ere the wound is closed not one may require a ligature; here, however, as in all other parts of the body, it is well to act on the safe side, and better, therefore, to apply two or three ligatures too many than one too few. The most of the branches of the portio dura will also be divided, and the features will be drawn to the opposite side in a conspicuous manner, though ultimately this condition will become less observable.

A fold of lint, small in proportion to the size of the tumour which may have been removed, should then be placed in the wound; over this the edges should be approximated, and held together by stitches of interrupted suture, a needle and twisted thread being, however, kept in the end of the wound, if one be made, at the margin of the lip. Some straps may be of service, by closing the intervals between the threads; and here, perhaps, the isinglass plaster may be advantageously used, as it is less likely to cause irritation than the common resinous adhesive kind. The saliva from the divided ducts of the parotid, and also from the sublingual and submaxillary glands, may be allowed to take its own course: perhaps it may flow into the mouth; possibly it may ooze in whole or in part through the wound at various points; but, in the latter event, the external apertures will ultimately close, although in some instances not till the lapse of several weeks or months.

Everything before, during, and after the operation, regarding the proper position of the portion of jaw which is to be left, the tongue, the dressing of the wound, &c., must be attended to and conducted according to rules already laid down in the introductory portion of this volume.

I have recommended the sitting posture as being most convenient, for the blood is thus permitted to escape from the mouth. Sometimes a patient will faint, and must then be laid on his back,—indeed, whether or not, it is always best to do so as soon as the disease has been removed. It has often happened that these proceedings have been retarded by sickness and vomiting; and considering their severity, I need scarcely point out the propriety of having wine at hand contained in a vessel (such as a teapot), with a spout of sufficient length to permit the contents being poured into the back of the mouth. In the present day these observations do not apply when chloroform is used; and in such cases I have no more hesitation in using chloroform than in any others where operations are required.

The accompanying drawing (fig. 382) represents the profile of a girl, from whom I removed a considerable portion of the lower jaw by disarticulation more than thirty years ago. My friend and former assistant, the late Dr. Richard Mackenzie, of Edinburgh, wrote to me regarding her condition eight years afterwards thus:—"The features are slightly twisted, but little or no paralysis exists. It appears as if the portio dura had not been divided. She can wink with either eye, and turn the mouth with nearly equal facility to either side. The
lower incisors are drawn considerably behind those of the upper, but she can push the chin forwards so as to bring the opposite teeth nearly into contact. The portion of the jaw which was removed is supplied by ligament, and the divided end of the bone cannot be distinctly felt."

As a rare event in a surgeon's experience, I may add, that I have verified the above account during an examination within the last few years of the same face, now that of a woman past the meridian of life.

In one operation of the kind above referred to, I had much annoyance from secondary hemorrhage about the fourth day. It was requisite to open the wound, when to my astonishment I found that the bleeding came from the upper end of the facial artery. On seuring it with a thread, the bleeding ceased, and the case did well. Hence the reason of my recommendation on page 587 to tie both ends at the time of operation.

Many years ago I modified the operations above described, in regard to carrying the incision through the lip. I doubt if this is ever required, and I am of opinion that any portion of the lower jaw, or even the whole bone, may be taken away without cutting the margin of the lip at all. However extensive the incisions, if the margin of the lip be left unintact, there will be less of the wound observable afterwards, and under the circumstances the labial artery will be left entire, whereby the loss of blood will be somewhat
less. In the case here represented (fig. 383), a large tumour was removed, including the lower jaw from the mental portion to the articulation, while the lip was not interfered with. The operation was not in any respect more difficult, but the result seemed more satisfactory than in other instances where I had divided the lip. The figure (384) gives a fair representation of the patient some months after the operation. In this instance my friend, Mr. Samuel Cartwright, ingeniously fitted in several teeth, to fill up a portion of the gap, greatly to the satisfaction of the patient, both as regarded appearance and the modulation of his voice, about which he was very particular and anxious, as he was a vocalist by profession. I perceive by The Lancet for 8th August, 1857, a patient from whom M. Maisonneuve, of Paris, lately removed the whole of the lower jaw, has had a substitute made for the bone and teeth by Messrs. Fowler and Preterre, dentists, of that city, which has seemingly been highly approved.

In this case the tumour, represented in figure 385, was a cyst with walls of various degrees of thickness. I had watched its progress for nearly ten years. The patient always entertained hopes that a cure might be effected without an operation, but at last had well nigh lost his life from a violent inflammation within the cyst, induced by a stimulating injection which had been introduced through an opening on the gum,—a practice resorted to by some one ignorant of the true nature of such a case, or the proper mode of dealing with it.

It does not appear to me to be necessary to describe such steps as might be required for removal of the whole of this bone, for the directions applicable to one side will suit for a similar proceeding on the other. Whatever bulk the tumour may be in any part of the bone, the whole of the skin should always be retained, for it will
soon contract, however much it may have been distended. Here, as in other resections, the operator must often be guided by the condition of the tumour in making his external incisions, and his anatomy will point out to him in what directions he may carry his knife with safety.

Since 1810, when Dr. Deadrick, of Tennessee, in America, first removed a portion of this bone, and in accordance with the example set to surgeons in Europe by Dupuytren in 1812, the operation has been very frequently repeated, with admirable success. The chin, the part sustaining the molares, the ramus, one half of the bone, two-thirds, and even the whole from condyle to condyle, have been separated. Among British surgeons few have done so much in this way as Mr. Cusack of Dublin: Mr. Liston has also operated in numerous cases; and Mr. Syme, in the last edition of his Principles of Surgery, gives a drawing of an enormous growth in this situation, "one of the largest, if not the largest, which has been removed in this way." The tumour weighed many pounds, and the operation for its removal was attended with signal success: years after, I saw this patient in excellent health, and a high stock covered the deformity so well that the loss of so large a portion of the maxilla was scarcely observable.

On thinking over one's experience, and reading that of others, it has often been a fancy in my mind that huge growths, such as were seen and described by others, would never again be seen by surgeons in civilized life, for the simple reason that, with improved surgery, all such monstrosities are expected to be checked in the bud as it were.
Yet here, as in other departments of surgery, I have recently, after an experience of forty years, met with more huge growths than I had ever seen before. Figure 386 shows the size of a tumour in the lower jaw of a gentleman, aged sixty, who came from South America to consult some European surgeons, and if so advised, to undergo an operation. He saw myself and Nélaton, and our opinions being similar, that eminent surgeon operated with perfect success. Not long after the ease represented in figure 387 came under my charge in King's College Hospital. The patient was in an exhausted state from protracted difficulty of swallowing and other annoyances; and I did not feel justified in recommending an operation. She died within a few months of sheer debility, and a post-mortem examination showed that so far as tissues or organs were concerned, an operation would have been quite practieable, although of course hazardous from
its magnitude. Even since this case was under notice I have seen one still more remarkable. It was under Mr. Heath's care, at University College Hospital, and the particulars have been published in that gentleman's work on the Jaws. By his kind permission I am enabled to give the likeness of it, represented in figure 388.

Hitherto all operations on the lower jaw, like those above described, have involved the mouth in some way or other, but a curious case of disarticulation of the ramus, including a small tumour, has been recorded by Mr. Syme, in the volume for 1843 of the London and Edinburgh Monthly Journal of Medical Science, wherein he succeeded by an incision in front of the ear in effecting separation without opening the mouth.

Occasionally abscess forms within the antrum, which is accompanied with great pain until an opening is made through the outer wall. There may be some difficulty in detecting the presence of matter; for, unless there be a considerable accumulation, and that for some time, too, the cavity will not alter at all in shape. In some instances, however, the outer (or anterior) wall may bulge forward, and fluctuation may actually be detected, in which case there need be no hesitation about making an opening at the most convenient part, either with a stout knife, punch, or trocar, as may be deemed best; but when the matter is encircled with firm bone, the condition may not be altogether so distinct, although from the general oedema in the cheek, the intense throbbing pain in the antrum, and perhaps rigors, the surgeon may generally suspect the true nature of the ailment.

Under such circumstances, he will seldom do wrong if he puncture the cavity immediately above the first or second bicuspid tooth. Before doing so, however, it will be best to extract any stumps or diseased teeth immediately below, as possibly the inflammation and suppuration may be at the root of a fang. With stumps removal should at once be resorted to; but if a tooth is sound, or tolerably so, it may be a question as to whether it should be removed or not. If there is great tenderness on pressing upwards it should be extracted.

Curiously, notwithstanding the multiplicity of modern additions to surgical instruments, not one of any note has been proposed to puncture the antrum. I can testify from experience that a stout knife, punch, or trocar, are at best but awkward tools for such a process. I have seen a good trocar and canula which would have answered for a hundred hydroceles spoilt with one thrust in this locality, doing the work awkwardly after all; but I have now great satisfaction in bringing under notice the ordinary modern carpenter's gimlet, as represented in figure 389.
This can be screwed through a socket, alveolar process, or front of the antrum, if the bone there is still hard, with unerring facility; and it has the advantage of scooping out a hole which will remain patent for a considerable time to come, and so permit a free discharge, such as is the main object of the operation. The instrument may be a quarter of an inch in diameter or more, in accordance with the seeming necessity of the case. A similar borer might be advantageously used in puncturing some of the large long bones, such as the humerus or tibia, where deep-seated abscess may be suspected.

Sometimes in suppuration here the alveoli become carious, and portions require to be removed, but no particular instructions about such operations seem at present required. I am inclined to imagine that necrosis is of more common occurrence in this situation than caries, and certainly if a disease begins in the latter form in the alveoli or any portion of the superior maxilla, it rarely terminates in any other way than in death of the part. I have repeatedly known extensive necrosis of the upper jaw cause such swelling of the surrounding soft tissues that the case has been mistaken for malignant tumour within the antrum. I do not think that much skill is required to distinguish between such conditions, nor does it need much knowledge of surgery to appreciate the difference between the two. In necrosis the surgeon must wait until the dead part is separated from the surrounding tissues, when it may be taken away with a permanently successful result, and by a process, too, far less formidable and dangerous than that for removal of a growth within the antrum. The sequestrum may be extracted entire or piecemeal through the mouth; but if there is a large solid tumour of the antrum it cannot be effectually dealt with unless the face be laid open, and the knife and cutting forceps extensively used.

Tumours of the upper jaw may, like those last referred to, be connected with the gums, the alveoli, the harder portions of the bone, or possibly with the interior of the antrum: indeed, making allowances for the differences in position, shape, and other physical characters between this and the lower maxilla, there is considerable resemblance between the diseases of each.

In certain instances an accumulation of fluid takes place in the antrum, which gradually expands the walls and causes the front part to project conspicuously. In such cases the opening between the antrum and the nostrils has probably closed, and the fluid within is chiefly inspissated mucus. I have seen instances of this kind cause great deformity. In one the antrum was expanded to the size of an orange, and in front the osseous wall had disappeared, but continuous with the lower margin of the orbit a plate of bone projected forwards and slightly downwards, and there was a corresponding plate projected from the alveolar ridge forwards and slightly upwards, both forming part of the large osseous shell into which the antrum had in a manner been converted. Figure 390 gives a good, and I believe unusual, example of this condition. The manner in which the antrum has been expanded forwards, and the plate of bone projecting on a
 Here the front of the antrum had been absorbed, and the cavity was covered by a kind of mucous sheath which lined the interior of the cheek. The large swelling in this case burst before death, and the cast from which this sketch is taken was made afterwards. In two examples of this kind, I have observed that when the swelling was at a certain stage, as the front wall of the antrum was being expanded, the thin plate of bone at the apex of the swelling could be felt crackling under the finger like strong parchment. In some of these cases, a puncture into the antrum above the alveolar ridge might suffice for a cure. In all probability it would be requisite to establish a permanent opening. Possibly this might be done from the nostril. In various patients I have cut away the front wall of the antrum with permanent benefit, and in certain instances such a step is the only one by which the deformity can be removed. Such a proceeding can be readily accomplished through the mouth, without interfering with the check in any way, excepting raising it for the time from the portion of the antrum to be taken away. The margin of the mouth may be cut or not at the will of the surgeon. If the lips can be left entire, so much the better, but generally it will greatly facilitate proceedings if an incision is made through the margin of the mouth; and for this purpose, I beg particularly to recommend the incision advised two pages further on for the removal of small tumours of the jaw. Strong bent scissors, or the semicircular forceps, already referred to at p. 383, will suffice to cut through the osseous wall.

A variety of circumstances will regulate the character of any operation which may be necessary for tumours in the face which involve the bones. On all occasions, whether in the lower or upper jaw, every care should be taken to make the external wounds, if any such be requisite, of a size so small and in such a position as to produce the least possible amount of disfigurement afterwards. At the same time the operator should not hesitate to make a free external opening should this seem needful at first, or be afterwards found necessary, and though it is impossible to place them where they will not in future be seen, the disfigurement from such wounds is wonderfully little, especially if compared with the projection occasioned by large tumours in this part of the face.

So far as my own experience enables me to judge, I should say that
small tumours connected with the gums and alveoli can be more easily removed from the lower jaw than the upper, without the necessity of any wound in the lips. In the vicinity of the incisors this may readily be done by the application of the knife and forceps, but further back any attempt of the kind will be attended with great trouble to the surgeon, and probably much pain to the patient (if chloroform be not given), in consequence of the stretching of the mouth and the necessity for more frequent application of the forceps than might be required, were there a freer external opening. Supposing an operation demanded for a growth of the size of a walnut or larger, situated towards the anterior part of the upper maxilla, and there being an evident necessity for a larger external aperture than the natural size of the opening of the mouth, it may be accomplished in the following manner:—The patient being laid on a couch or table, or seated, with his head supported by an assistant, or against the back of a chair, an incision should be made with a scalpel or bistoury from the margin of the upper lip to the root, exactly in the middle line up to the columna, and here it should diverge into the nostril which is most directly over the tumour; now the mucous membrane and cheek should be dissected off the tumour as far upwards and backwards as its bulk renders necessary; then an incisor tooth and a bicuspid or molar must be extracted, and the point of the knife carried through the mucous membrane of the hard palate and every soft texture which it can reach, where it is intended to effect the separation: next a small saw (fig. 391), (similar to that usually termed Hey's, or those figured in Scultetus), should be applied to notch the alveolar ridge in front and behind, and it may be well also to make a groove above the tumour. Such a saw, from its limited length, and also from the narrowness of the stalk between the blade and the handle, can be more readily used in this locality: then the cutting forceps should be applied, and the separation thereby completed. The different shapes of forceps already so frequently alluded to (pp. 583, 588, and elsewhere), may be of great service on such an occasion, as, from the manner in which the blades are bent near the handles, they may be applied to some parts more conveniently than those which are straight.

If the tumour is solid throughout, the whole mass must, if possible, be included in these sections; or if any part remains, it must be cut away with the forceps or gouge. Sometimes swellings of considerable size form in the alveoli here, which contain fluid of a serous character; if, therefore, there is any reason to suspect one of this kind, it might be advisable, as a preliminary step, to puncture it through the gums with a knife, trocar, or gimlet (p. 595), and should the disease prove so, it may be possible to cut away a portion of the anterior wall of the cyst without interfering with the lips at all. I have seen one instance where
this might have been advantageously done. The nature of the tumour was mistaken, however, and only discovered during the steps of the operation after the external incision had been effected. In this case the crown of an incisor tooth was found in the upper and back part of the cyst, a circumstance which I have repeatedly observed in such operations on the adult living body. Were a cavity laid open as above alluded to, the future treatment should be conducted in the manner already described for similar cases in the lower jaw.

In puncturing a tumour it is possible that but little resistance might be offered to the progress of the instrument after the outer shell had been perforated, but it would be wrong to conclude on that account that it is a cyst: it might be a soft gelatinous mass, or one of a medullary character,—in the gum, alveoli, or possibly within the antrum, and in such cases there need be no hesitation about the propriety of removing the entire disease, supposing it to be within reasonable reach, and the circumstances otherwise favourable.

Since the second edition of this work was published, I have usually performed the operation as above described. Prior to that date, after the usual incision over the prominent part of the tumour, I had remarked, in all the instances which had come under my notice, that the scar in the lip or cheek was very conspicuous, and it seemed to me that it might in a great measure be avoided or concealed. I soon tested the views I had formed, by operating in the following manner. Instead of cutting the cheek or lip under the ala, I slit the latter open exactly in the mesial line in the hollow under the columna, and then carried the knife along one side of the base of the columna into the nostril next the tumour: I then proceeded with the operation as above described. By opening the nostril in this way, as much relaxation was gained as if the knife had been carried from the root of the ala an inch up the side of the nose, and as much facility was given for the future steps of the opera-
tion, as if an incision of perhaps three inches in length had been made through the lip and side of the nose, while a grand object was gained of leaving the slightest possible conspicuous appearance afterwards. The mobility of the apex of the nose contributes greatly to the facilities claimed for this incision. I found that through such an opening I could do all that was required as readily as by the other incisions above referred to, or even by the method of laying open the cheek afterwards described. I have now in numerous instances removed the greater part of the superior maxilla with this comparatively limited incision, and I earnestly recommend the plan in preference to any other with which I am acquainted.

Fig. 392.

Besides such a saw as that last delineated, I have found one of narrower dimensions, like figure 392, of service, and a semicircular blade like figure 393 has also proved of great use. In several
instances, too, I have found it of advantage, when it was necessary to remove much of the palatine plate, to dissect the soft tissue in the roof of the mouth, from the tumour towards the mesial line, with such an instrument as that delineated in fig. 345, at p. 526, by which proceeding the gap left has been smaller than if the soft tissue had been taken away in the same line as the bone.

Fig. 393.

The size of the tumour may from the first make it apparent that more extensive incisions than those yet described will be required. The swelling may not only protrude in front, but it may be observable both in the mouth and nostril, and by the elevation or protrusion of the eyeball it may be apparent that it also extends upwards: there will in many instances be difficulty in appreciating the extent of the disease backwards, whilst in others there can be none in perceiving that it protrudes into the posterior nares and occupies the upper part of the pharynx. It will often be a nice question to determine how far the tumours are malignant or otherwisc, and even when such a conclusion is drawn, the further question as to the extent of their surrounding attachments may demand serious consideration. As to certain of these features the reader is referred to the Chapter on Tumours; but there are many circumstances connected with the growths under consideration which demand some separate notice here. Most seem to have their origin in or immediately about the antrum, and when the growth is actually within, the cavity will, in all probability, be filled ere there are any prominent external symptoms, and when, therefore, it does protrude in any direction in which it is first most readily detected, the chances are, that it will also have encroached more or less on the opposite parietes. But it is often difficult to ascertain the exact origin of the disease; for although, to all appearance, it occupies the whole of the antrum, it may be connected with only one or other side of its circumference. Fortunately, in many instances it will be in front; it may, however, be behind and above; again in others it may involve almost the entire extent of the superior maxilla, and in all, as it increases in size, the external projection will become more and more apparent. Softness and rapidity of growth are, in my opinion, most indicative of malignity in such cases; and if combined with these, the limits are indistinctly defined, and there are constitutional indications of such a growth, the disease is evidently one of a serious character. If, on the other hand, the swelling is hard and slow of increase; if the distinctions between it and the surrounding parts are apparent; if the person seems otherwise in good health, and in nowise disturbed by the swelling excepting by the inconvenience resulting from its bulk, then there will be every reason to suppose that it is benign in character. But, as already stated, there may be doubts about its connexion behind and above, and now possibly the history of the disease may throw some
light on this feature; for, if the swelling has first become conspicuous in front, and then gradually extended backwards along the palate, and upwards and inwards to the nostril, whilst there has never been deep-seated uneasiness, or pain, or feeling of obstruction in the back part of the nasal passage, there will be good reason to suppose that it has no intimate connexion with (i.e., that it does not involve) these parts. Even yet, however, the surgeon should not be contented, and before giving a decision, should pass a probe along the nostril to ascertain if the passage be clear; he should also carry the point of his finger behind and above the soft palate so as to make a careful examination there too, and if he finds that there is no swelling, or only a round solid mass similar to that in front, with the fissure distinct (however small) between the tumour and the base of the cranium, he may be well assured that the growth involves only the superior maxilla, or, at most, part of the palatine, spongy, and malar bones.

But cases occur which in their early stages the most experienced may be uncertain about, and growths will sometimes project of a great size externally, whose deeper connexions cannot be ascertained until an operation is performed. Sometimes, however, enormous tumours will protrude on the face from the upper jaw, when, nevertheless, the hard palate, especially the palatine plate of the palatine bone, the inner walls of the antrum, and the floor of the orbit, are so natural in condition, that it is impossible to deem the growth deep-seated. In the museum at Netley there is a specimen of a large osseous shell connected with the anterior wall of the antrum, which, doubtless, on the living body, must have produced a hideous appearance, in which maceration shows that almost the entire of the hard palate, the inner, upper, and posterior walls of the cavity, are in a natural condition. But perhaps few cases so well illustrate the enormous magnitude which such tumours will sometimes attain without involving the deeper parts of the bone, as that referred to and delineated in Mr. Liston's Practical Surgery, where the diseased mass extended from the eyebrow to below the level of the lower jaw, and yet the textures behind are not implicated; for the entire disease, weighing several pounds, was most successfully extirpated, and with greater facility, too, than with others of less formidable size. In Dupuytren's collection there are remarkable examples of large growths in the superior maxilla, some unconnected with the parts behind, others extensively so, and some involving a considerable portion of the frontal bone: several of these are exhibited in the published catalogue of the preparations: but indeed there are few museums nowadays which do not contain examples of the kind. Several such are delineated in the volume of my lectures on this subject at the College of Surgeons, and Mr. Heath's work is still more amply illustrated.

Supposing a tumour connected with the upper jaw of a larger size than that for which I have yet described an operation (p. 598), and that a proceeding of the kind is necessary, it may be accomplished in the following manner:—The patient should be lying or seated, with his head as previously described: an incision should be made from
the margin of the upper lip towards the nostril, and then from the ala, as high as within half an inch of the inner canthus of the eyelid; next the cheek should be laid open from the angle of the mouth (or near it) as far as the zygomatic process of the malar bone, and, if necessary, an incision at right angles with this one should extend from the external angular process of the frontal bone, towards the neck of the lower jaw; now the flap between the nose and the wound in the cheek should be dissected off the tumour, and turned upwards on the temple; then that portion of the cheek below and behind the wound should be turned downwards, and the mucous membrane divided, so as to expose freely the interior of the mouth. The extent of the disease being now more appreciable, provision may be made for the application of the saw and forceps. An incisor tooth, perhaps two, may be extracted, and then the lining of the hard palate should be cut parallel with the side of the tumour, as far back as the soft palate, at whose anterior margin a transverse division should be made between that just effected and the back of the last molar tooth; then with one or other of the saws already referred to (pages 598 and 599), the alveoli and palatine plate of the superior maxilla should be notched,—almost divided,—either from below upwards, or from above downwards, in which latter case a narrow-bladed saw, like that represented in figure 392, will be found of great service within the nostril, when the cutting forceps should be used to complete the separation. But before the saw is laid aside, the operator should ascertain what may be required above; for if the malar bone is sound, and also the orbital plate of the superior maxilla, they should both be left; and for this purpose a notch must be made with the saw across from the nasal process of the latter to the outer margin of the former, and then the forceps should be used, first to complete the division between the mouth and nose, next to cut through the nasal process of the superior maxilla, and then to pass along the horizontal groove already made with the saw, below the orbit. If, on the other hand, it is found impossible to save any portion of the os male or of the floor of the orbit, the saw need not be used after its duty has been fulfilled on the hard palate; but the forceps, after having succeeded it here, must be applied to divide the nasal process of the maxilla between the nostril and inner side of the orbit, then to the zygomatic process of the malar, and lastly to the frontal process of the same bone, when the tumour should be seized with the fingers, or grasped with such forceps as these (fig. 394),—which, years ago, I had constructed for the purpose, and forcibly depressed so as to cause it to start from its place; this being accom-
plished, a few additional touches with knife or scissors will divide the remaining soft textures and permit separation. If the orbit has to be opened the eyeball, and its appendages must be carefully held out of the way of the forceps and fingers.

In such operations the surgeon has been recommended, in making the wound on the surface, to stand in front of the patient; but in applying the saw to the roof of the mouth, it will possibly be found best to stand behind, and if so he must change his position; indeed, he must move about in such a way as to suit his convenience; for the surfaces are so irregular that he is obliged to do so, else he will cramp the movements of his own hands. From custom I now almost invariably stand on the right side of the patient for tumours on either side, and if I use the saw for the hard palate and alveoli, I apply it as frequently through the nostrils as by the mouth.

The incisions through the cheeks are generally accompanied by profuse bleeding, but it soon ceases from the small vessels, and the facial can be commanded at first with the fingers and afterwards with a ligature. The vessels behind never give trouble, unless part of the tumour has been left after the larger mass has been removed; and in such a case the actual cautery may possibly be required. I once saw Sir George Ballingall use several round-headed cauteries here (p. 63), in an instance where he removed a large growth from the site of the antrum, when a portion of it was found to be so deep, that it was deemed advisable to endeavour to destroy it in this way, and when, moreover, the hemorrhage was so copious that the heated iron was considered requisite to stem the flow. It has occasionally been the custom to tie the common or the external carotid before proceeding to attack such growths, but experience has proved that this is altogether unnecessary. Before the branches of the internal maxillary reach the back of the tumour, they are so small, that when cut or torn across the escape of blood is trifling.

It is scarcely necessary to observe that in the early part of the operation the infra-orbital nerve is cut as it passes out of its canal: at the latter stage, as the tumour is being turned out, the nerve should be divided at the back part of the floor of the orbit to prevent it being dragged or torn. Nor need I do more than remark that, as the gap is now great between the tongue and the eyeball, it is necessary in dressing the wound to fill the cavity with lint: this being advisable both to assist in restraining bleeding, as well as to keep the eyeball from falling too low, and the cheek from sinking too much in. The wounds on the surface must be accurately brought together by the interrupted and twisted suture; and as the interior has to heal by supuration and granulation, the subsequent treatment must be through the mouth.

Drawing 395 exhibits the face of one of my patients, with the lines of incision: the lower end of that on the cheek I should, however, prefer to terminate at the angle of the mouth. The tumour, though sufficiently large to cause great deformity (rather more, in fact, than is here represented), was far from being of that magnitude at which
they occasionally arrive. It was fortunately of a hard description, more, in fact, like an exostosis than what is usually called osteosarcoma, and although firmly fixed, in consequence of the thickened state of the surrounding processes of the bone, was successfully dislodged, and months afterwards the girl's appearance was as represented in the next likeness (fig. 396). The patient was under my care in King's College Hospital; her case was published in The Lancet for February and March, 1842; and, after the lapse of several years, her countenance was still further improved. At a later date when I saw this girl she was still in perfect health, and although there was no return of the disease, there was considerable hypertrophy of the processes of bone which had been cut across—a condition which was somewhat conspicuous at the time of the operation.

As a contrast to the last figure, I here (fig. 397) give a representation of the face of one of my patients, whose jaw and malar bone, which were involved in a large tumour, I removed by a single incision through the cheek, as displayed by the cicatrix. I have subsequently, however, done as much through an opening, such as is recommended at p. 599, and in order further to illustrate this proceeding, I beg to call attention to this cut (fig. 398), which displays the appearance of a girl's face some time after an operation had been performed for a tumour in the superior maxilla. Here an incision, about an inch long, had been made from the angle of the mouth up the left cheek, but it is doubtful if the disease had been effectually removed—for the growth returned within twelve months. The scar, at any rate,
remained conspicuous ever after. In the operation which I performed, the knife was carried in the mesial line of the hollow of the lip, and since then, now many years ago, there has been no return. Here I shall again observe (p. 599) that the line in the centre of the lip not only gives as much space as that indicated by the cicatrix, but that in addition it permits advantage being taken of the natural opening of the nostril, which at once gives a space equal to the length of the incision in the lip, and so by the mobility of the tip of the nose permits a large opening in the face, through which almost any ordinary size of tumour may be extracted. The great superiority of such a proceeding over any other incision on the face for operations on the upper jaw is, that the scar, from being in the hollow of the furrow under the columna, cannot be seen excepting on a very close scrutiny in front.

In the instance next represented (fig. 399) the front of the antrum was taken away through such an incision as that above referred to, and the result gave great satisfaction. I have seen my friend, Mr. Henry Smith, remove a large portion of the upper jaw in this way, and some interesting particulars of the case have been pub-
lished by him in the Medical Times and Gazette for 17th April, 1852.

Since the last edition of this work was published I have rarely performed any other operation on the upper jaw,—wherein it has been needful to remove large portions, possibly the whole of the bone, including the malar,—than that by the mesial incision, and with the curved forceps (fig. 372, p. 583); but in some cases, where the tumour has been beyond ordinary limits, or where a free space has been deemed requisite, I have found great advantage in enlarging the wound thus: the knife has been carried from the root of the ala along the side of the nose—between it and the cheek—as far as the nasal bone, and then it has been directed in a horizontal line opposite the inferior osseous border of the orbit, to the zygomatic process of the malar bone; here it has stopped, or a line at right angles has been made, with the object of giving facility to reach the attachments and circumference of the tumour in this locality. These incisions give, in my opinion, greater space for the removal of disease than any others, such as were recommended by Gensoul and Lizars; they do not involve any large vessels, and the scars resulting are less conspicuous than from any others. Figure 400 illustrates the lines of incisions here recommended.

Operations for the removal of tumours connected with the upper jaw are by no means so modern as some imagine. Such a proceeding is said to have been accomplished so far back as the seventeenth century; and about the middle of the last one Charles White, of Manchester, removed a large growth from this situation. The disease was of a soft character, interspersed here and there with spiculae of bone, and such as from its external appearance and history the modern surgeon would not feel
plied the greater part of the left side of the face, extending from the lower part of the jaw to the top of the forehead, and from the furthest part of the left temple to the external canthus of the eye," the latter organ "being thrust out of its orbit, so that it lay on the temple." The tumour was partly cut, torn, and scooped away; and although "the optic nerve was denuded as far as the dura mater, and this membrane, and the pulsations of the brain were apparent," and though the patient "was so incommoded by the fetid matter flowing into her mouth, that she was obliged to lie on her face several weeks, to prevent suffocation," she ultimately made an excellent recovery, retaining at the same time the use of her eye. These proceedings were, however, very different from those which characterize what may be called the modern operation. Instead of cutting into the mass, the surgeon now usually cuts beyond the disease, just as when he is removing a malignant growth elsewhere; for, although he may feel assured that, strictly speaking, the disease may not be so, he generally acts as if it were, especially as in many instances it will be difficult to decide the question, and, accordingly, then, he selects for division the processes of bone on the circumference of the tumour, and thus removes the whole, or the greater part of the maxilla at the same time. Dupuytren claimed to be the first to propose and execute this operation, and beyond a doubt it was first performed in this country by Mr. Lizars in 1826; since then it has been frequently repeated by our own countrymen, and in all parts of the world where surgery is cultivated. M. Gensoul's name also stands high in the modern history of the proceeding; but such operations have now been so often and so successfully accomplished, that I need not refer to other names on the present occasion.

The incisions through the integuments may be modified according to circumstances,—a knowledge of anatomy and the shape of the tumour will usually determine them. Some operators have preferred certain incisions to all others,—for example Dieffenbach has left the cheek alone so as to preserve the branches of the portio dura, being content with an external incision through the upper lip and along the back or prominent part of the nose, up towards the inner canthus, from whence he has carried the knife horizontally along the lower eyelid to the upper and outer part of the malar bone; Gensoul has preferred three conspicuous incisions on the cheek; Warren, Velpeau, O'Shaughnessy, and others have been content with a single line from the angle of the mouth to the zygomatic process of the malar bones—a method which I have seen practised forty years ago by Sir George Ballingall in the Edinburgh Infirmary; Mr. Lizars, instead of approaching the os mala with his external wound in the cheek, carried it horizontally outwards on a line with the mouth. Mr. Liston combined with the long wound in the cheek an incision along the zygoma; but it were useless to refer particularly to all, and certainly in my own practice I should not limit myself to a particular set of incisions if I saw good reason to act otherwise. It is, I believe, the invariable custom to dissect the cheek from the surface of the tumour before
applying the saw or cutting forceps; but I have often thought that, when it seemed desirable to save blood, the two processes of the malar bone, the ascending process of the superior maxilla, and even the alveoli and a considerable portion of the palatine plate of this bone, might all be notched, if not fairly divided, before making the long wound in the cheek, from whence the greater part of the blood escapes. Such a process would certainly be more troublesome, and require more skill on the part of the surgeon, but were it cleverly accomplished, there might be some advantage gained by thus getting over what may be deemed some of the most difficult steps of the operation in an early stage of the proceedings, and before the most vascular parts are touched. Twice in the same case, at different periods, have I known a bold surgeon obliged by the bleeding from the cheek to desist from further interference. Mr. O'Shanhnessy, in his excellent essay, On Operations on the Jaws, has strenuously urged the propriety of saving all the skin over such tumours, however much it may be stretched by the largeness of the growth,—a doctrine in which I cordially agree, for it will speedily contract so much, that if unfortunately a portion has been taken away, a gap must be the result, as I have actually known. On this latter subject and on many others connected with disease of the jaws and operations for their removal, I may again refer the reader to my lectures on such subjects, at the College of Surgeons, and in particular to the admirable work of my friend and former pupil, Mr. Christopher Heath, which contains the greatest accumulation of knowledge on these subjects hitherto published in a collected and specific form.

I believe that there are few matters of importance which have been omitted in this section of the Head and Neck. Of what is usually called Dental Surgery I have made no special mention; nor have I dwelt at much length either upon the Eyes or Ears, as the treatment of the affections of those organs is in many respects deemed each a separate department of surgery; what I have omitted otherwise may, I imagine, be easily understood by any one versed in a knowledge of anatomy and the principles of surgery. For example, chiefly in consequence of the arrangement followed with reference to the face, I have had no proper opportunity of making allusions to the division of the branches of the fifth pair of nerves as they issue from the respective foramina above and below the orbit, and on the chin. Any one acquainted with anatomy can have no difficulty in effecting such proceedings by subcutaneous incisions, and a knowledge of pathology and surgery will sanction the use of the knife, when it is found that the painful disease, tic-douloureux, resists all other means. Indeed, the affections of the nerves in this situation appertain so much to the practice of physic, that I have almost purposely omitted any notice of them. To show, however, the student the value of a correct knowledge of anatomy, whether he intends to be physician or surgeon, I shall, besides recommending to his attention Sir Charles Bell's work on the subject, refer to a case which was in King's College Hospital, under the care of my colleague, Dr. Todd. The patient had lost all
power of raising the upper eyelid on one side (the affection termed ptosis), and in addition had no power in moving the eyeball, excepting in performing abduction of the organ. Here one ignorant of the groundwork of pathology—anatomy, would have been totally unable to account for the lively action in this direction, when a first year's student might perceive that, whilst there was an affection of the third pair of nerves, as indicated by the paralysis of three of the recti and levator palpebræ muscles, the sixth retained its functions, and gave power to the external rectus.
PART V.

OF THE CHEST, ABDOMEN, AND PELVIS.

CHAPTER I.

SURGERY OF THE CHEST, ABDOMEN, AND PELVIS.

In accordance with the arrangements throughout this volume, the surgery of the section now under notice must here have some separate consideration.

There are few points connected with the surgery of the chest which cannot be readily appreciated by the anatomist, and one already familiar with surgical doctrines. Wounds, dislocations, fractures, all come under the same category in this respect, for although much has been written in reference to such subjects, they can only be thoroughly understood and managed by the well-educated surgeon, and many of the little peculiarities and points of distinction drawn by authors are more to be attended to as the special fancies of the writers, than as involving any great and generally applicable doctrines different from those belonging to the province of surgery.

Wounds of all usual kinds, such as are referred to in the first section of this volume, may be observed on or in the chest. Superficial wounds require no special notice, and whilst I admit that penetrating and deep lesions are of vast importance and interest, I must still refer to other parts of this volume to make amends for what must appear defective here. A wound of the pleura is of importance as regards the structure involved, yet the chief feature of the case is in regard to the injury done to the cavity of the chest. If much hemorrhage occurs into the serous cavity evil is likely to befall, and the lung from being functionally affected may become physically so. Similar remarks apply to those cases of wounds of the chest, which permit the entrance of air into the cavity of the pleura. The latter case may be deemed of less serious importance than the former, but in either there is often such complication that the features referred to sink in importance when compared with others which may be conspicuously present. A wound of the lung, of some great vessel, of the heart, a complicated fracture, especially of the spinal column, or the presence of a foreign substance, may all give great complexity;—yet such cases can only be thoroughly appreciated by the anatomist and one conversant with the general principles of surgery.
The results peculiar to some of the injuries above referred to belong as much to the province of physiology as surgery, and although I am of opinion that the surgeon should be as competent to deal with such cases as the physician properly so called, I think it is not requisite to take up the subject here.

Fractures of the bones of the chest are of little importance merely as such, but should the pleura or lung be wounded, in conjunction with fractured rib, the case may prove a very serious one, and in examples of fracture of the dorsal portion of the spinal column, the accompanying lesion of the spinal marrow will form the chief feature of the injury, and will doubtless determine the result of the injury.

Wounds of the abdomen are probably of more frequency than those of the chest, especially such as penetrate the parietes, and this may be accounted for by the comparatively unprotected state of the viscera of the abdomen.

Modern experience has gone far to prove that there is much less hazard in a wound of the peritoneum than was formerly supposed. In whatever light the various operations for disease of the ovaries may be looked upon, they must be allowed to have given ample evidence that the peritoneal cavity can be opened with greater impunity than surgeons had any idea of. Notwithstanding the unquestionable success of many of the operations referred to, it ought not to be overlooked that wounds of the peritoneum are of very serious importance. There is a danger in penetrating wounds of the abdomen which may be said not to be present in any other cavity. Here blood may be effused as in other serous surfaces, and such a result may be attended with danger, both in respect to quantity as well as physical influence. In the chest the escape of air from the lungs, or its direct entrance into the serous cavity, may have a most serious effect; but if the stomach or any portion of the intestinal tube be wounded so as to permit the escape of ever so small a portion of their contents, the condition may be said to be beyond the surgeon's power, and there is hardly a chance of life. Foreign substances—such as bullets, may pass into the abdomen, as into the chest, with impunity in certain rare instances, but if any substance escapes from the alimentary tube into the previously healthy peritoneal cavity, the result will almost certainly be fatal.

Much interest has been attached to wounds of the intestines, and various opinions have been given as to the treatment and mode of practice in such cases. The doctrines referred to have been extensively illustrated by experiments upon the lower animals. I maintain that in this department, as in all others pertaining to surgery, the properly educated surgeon should here have his knowledge intuitively as it were. A fixed rule for all such cases cannot be laid down; the management must be left to the discretion of the surgeon; and a reliance upon the general principles of surgery will be more likely to produce good results than a reliance on a dogma, which may possibly not be applicable to the case. Perhaps I may err in thus
referring to such injuries, and possibly this may arise from my want of experience in cases of the kind. I believe I am not wrong, however, in stating that instances of the sort occur but rarely in civil practice, and when these do come under notice the circumstances are usually such as need no special directions beyond those precepts which belong to a knowledge of the science of surgery, founded on anatomy and physiology.

Some interesting questions as to injuries of the peritoneum and intestines in cases of hernia frequently come under the surgeon's consideration, and these will be duly referred to in future pages. It may be worthy of remark here, that while every recent year in modern times has afforded proof that wounds of the peritoneum are not so dangerous as had been imagined, and that whilst this membrane has been freely dealt with by many who are not in the habit of practising surgery, many of the regular surgeons have endeavoured to show that a supposed great danger of the ordinary operation for hernia, viz., that of opening the peritoneal cavity, may and should be avoided, and the division of the stricture without opening the hernial sac is the practice which has been recommended in consequence. Due notice will be taken of this practice in the latter part of the volume.

Perhaps the pelvic region presents more features of interest to the surgeon than either of the two above referred to. Fractures may be deemed of more interest, as they may in reality be treated merely as fractures, although even here the main features connected with such cases must be the amount of injury of the tissues and parts within the cavity. Fractures of the pelvis are usually accompanied with so much contusion, that the external indications of the latter condition are generally very conspicuous; indeed, in many instances of blows or falls upon the pelvis, the ecchymosis is so remarkable as to excite particular attention.

It is, in my opinion, scarcely correct to refer to dislocations of the bones of the pelvis, merely as dislocations: they ought to be considered more as fractures, for the separation of bones can hardly be deemed the principal feature of such cases, and in reality, if separation of articular surfaces be present, the injury is in all respects as bad, if not worse than a fracture. A mere displacement or fracture in the coccyx may not attract much attention, and of course I do not here refer to those partial separations which occasionally occur at the symphysis pubis, and the junction of the osa innominata with the sacrum. Perhaps a greater amount of violence is required to produce a dislocation than a fracture, but in either instance the damage to the neighbouring structures has more importance in giving character to the injury than any other feature, as, for example, wounds of the hip-joint and of the rectum, but especially of the bladder. Of all the viscera here, this is most apt to suffer, and if there be laceration, and its usual consequence, infiltration of urine, there is barely a chance for the patient. In such instances, the propriety of introducing a catheter into the bladder, to permit the ready escape of the contents, must be evident to the youngest in the profession.
Various diseased conditions of the viscera and organs connected with the pelvis, are of the utmost importance to the surgeon, and although most of them will be specially noticed in future chapters, I deem it requisite to refer to some of them at this stage of my task.

It is difficult, in such an arrangement as has been followed in this volume, to decide where syphilis and the various forms of venereal disease should be noticed. The primary forms of these affections are almost invariably met with in the region under consideration, yet they show themselves in such a variety of places and aspects, that they should be referred to with greater propriety, perhaps, in the first section of the volume. Indeed, I have no hesitation in stating, that the judicious management of these diseases, in all their different forms, must be conducted on those data which constitute the principles of surgery. It need scarcely be mentioned here that such diseases have been the most fruitful field of empiricism, and it has often appeared to me a questionable point, whether the educated medical man has not, in many examples, committed himself in this character, almost as deeply as the charlatan.

Gonorrhœa and syphilis in their primary forms of suppuration and ulceration can be best treated, in my opinion, by reference to general principles. That every now and then a gonorrhœa is cut short by an astringent or caustic solution must be admitted, but it is more the result of chance than judgment, and I have no doubt that in many instances where it has been supposed that this has been the case, gonorrhœa has, in reality, not been present. If the evils following attempts to arrest the discharge (in males particularly) were placed in comparison with those resulting from permitting the disease to take its course, it may be doubted if such attempts should be made at all. In syphilis, when a chancre is unequivocally present, Nature must have her way; and any attempt to thwart her must be followed by mischief. An excoriation may be seemingly affected or "cured" in a few hours by an astringent lotion, but a chancre never can. It must go through its various stages of suppuration, ulceration, and granulation ere it can cicatriz. In such a disease the surgeon's judgment will be best shown by averting such measures and applications as are likely to interfere with the regular progress of the actions referred to. Such observations as these may be said to constitute common-place truisms in surgery; yet, whilst willingly admitting this, I take the liberty of stating that, in my opinion, there has been far too much reliance placed on so-called specific treatment in such a form of disease. That mercury is of important use in certain cases of chancre, and in certain constitutions, cannot be denied, but that it is essential to the effectual cure of all such instances I cannot give assent. I consider it a part of my good fortune that I was a pupil of John Thomson's, and although I do not hold myself adverse to the administration of mercury in all instances of syphilis, I avow my belief that, in many instances, if not in most, it is as well and as successfully treated without this drug. But discussions on such topics are in a manner foreign to my present purposes. If they are not
considered so, my views may be ascertained in the first section of the volume: but to speak more closely in accordance with my own ideas, the principles of physic are as applicable here as those which may be said to be peculiar to surgery; and as I do not profess to teach all branches of the healing art in this volume, I must refer the pupil, or surgeon, to the knowledge which he should possess in this department of medicine. What may be called the surgery of venereal diseases may be readily understood by one acquainted with the principles of medicine. The medical view, strictly so called, admits of questions which will probably never be settled, and which, at all events, I have no disposition to take under discussion at present.

Disease of the scrotum and testicles constitutes an important part of the surgery of this section of the work, and I fear that the following pages will be deemed defective on such subjects; yet here I must again refer to the doctrine so frequently inculcated in various parts of this volume, regarding the true principles of surgery. A knowledge of anatomy, and also of the doctrines referred to in the first section of this work, makes the appreciation of such cases comparatively simple and correct, but as my space is limited, as regards the thickness of this volume, I must here refer particularly to the subject of tumours, and to the sketch of diseases of the mamma in the second section, for further information on the general question of tumours in the regions referred to. As regards certain special points, some observations will be found in future chapters which may serve the purposes of those who choose to consult this work.

Diseases in and near the anus are of very common occurrence, and their treatment has been deemed by many sufficient to constitute a special department in surgery. Whilst, in large towns, there need be no objection to such subdivisions, it ought to be the duty of every surgeon to make himself familiar, to the utmost of his opportunities, with such cases. There are fewer of such forms of disease met with in hospitals than of most others requiring surgical treatment; the reason being that those who suffer most frequently are found in the classes in society, who do not require to seek assistance at such institutions. But although the young surgeon may, during his pupilage, have seen but few, comparatively, of such cases, he can have little trouble or difficulty in appreciating their nature when they come under his notice in practice. The surgery of most of such cases will be practically, and, I hope, usefully described in future pages.

The diseases of the prostate, bladder, and kidneys belong as much almost to the physician as to the surgeon, and many of them can only be treated by the latter in that mode, which is considered to constitute a prominent feature in modern surgery, viz., the constitutional treatment of local disease. Whilst cordially agreeing with this doctrine, I do not, however, consider that such topics come properly within the scope of this volume, and whilst the modern surgeon must, in the course of his education, become somewhat familiar with the admirable works of Prout, Willis, Brodie, Golding Bird, Coulson, Crosse, and Gross, I deem it most in accordance with the objects of
this work to limit myself chiefly to the surgery, strictly so called, of such organs. In this sense the surgery of the kidneys needs no special comment here, but that of the bladder, prostate, and urethra will meet with such consideration in after pages as the limits of the volume will permit.

CHAPTER II.

DISLOCATIONS. FRACTURES. INCISIONS. LIGATURE OF ARTERIES.

Dislocations (in the ordinary acceptation of the term) are rarely met with in the chest. Occasionally the cartilage of one or more of the ribs may be loosened or driven inwards by great violence from the sternum, or there may be similar separation between the rib and cartilage. These injuries may be unaccompanied with others; but most frequently they only form part of a severe bruise of the chest, and are in conjunction, perhaps, with broken ribs, wounded lung, and injured spine. Sometimes the posterior end of a rib is detached from the spine, but this is even more rare than the last, as the shaft is so much more likely to give way.

It is scarcely possible to imagine a dislocation between the vertebrae on the dorsal region: they are certainly separated in some severe injuries, being usually, however, broken at the same time; but here the principal feature will be with reference to the spinal marrow and the violence otherwise done to the spine and neighbouring parts.

Fractures of one or other of the bones of the chest are of much more frequent occurrence: indeed, the ribs, perhaps, suffer more frequently than any other bones. There is seldom much difficulty in detecting such an injury; the fall or blow which has occasioned it, and the subsequent pain, will excite suspicion; possibly the patient may feel the surfaces grating as he breathes; but, at all events, the application of the fingers will put the circumstance beyond doubt. Sometimes, however, the examination gives so much pain that the surgeon may not deem it necessary to be very minute, nor is there an absolute necessity for being so, for whether there is fracture or only contusion, the treatment should be nearly the same.

When the sternum is broken there will seldom be difficulty in perceiving the fissure, though there may possibly be but slight separation, and very little mobility. Sometimes the outer table of this bone is driven into the cancellated structure without fissure occurring; but unless complicated with other injury, such an instance, supposing it to be detected, would not differ in any material respect (so far as regards the treatment) from a severe contusion.
In dislocations of the ribs, as above referred to, and in fractures, whether of these bones or of the sternum, the surgeon has little else to do than to encircle the chest with a broad flannel roller, so as to keep the fragments steady during respiration, which process will then be carried on almost entirely by the movements of the diaphragm and other abdominal muscles. In the course of ten or fifteen days the bandage may possibly be dispensed with, although it will often be required much longer. The necessity for watching the state of the pulse and other precursory symptoms of inflammation should not be overlooked on such occasions, as the excited action in and around the seat of injury may perhaps extend to the pleura. Leeches to the part, cupping, or even general blood-letting, may possibly be requisite. It cannot be doubted that in many of these injuries the pleura must be lacerated, and in such cases the probability of bad results should always keep the practitioner on his guard.

Besides injury of the pleura costalis, it not unfrequently happens that the pleura pulmonalis, with a portion of the lung itself, is injured, in instances of fracture. Here the circumstance is generally made manifest by the escape of air from the lung, and perhaps, too, by the appearance of blood through the aérial passages. The latter circumstance is not always to be depended upon as indicative of the lung having been torn by a spicula of bone; but when there is a fracture without any object having penetrated the chest from the surface, accompanied by the escape of air, there can scarcely be a doubt about the mode in which the lung has been torn. The air at first escapes into the cavity of the chest, in all probability, during expiration; then, as it accumulates, gets through the fissures in the pleura costalis, and makes its way between the fragments into the cellular texture around, from whence it spreads in all directions under the skin so long as it continues to escape from the lung. This condition, which is technically called emphysema, more frequently follows penetrating wounds involving the lungs; but when present in fracture it calls for additional vigilance on the part of the surgeon. Its presence in the subcutaneous cellular tissue is readily detected by the fingers; the feeling of crepitation, such as when air forms during putrefaction in the dead body, can never be mistaken. Sometimes even swelling is conspicuous, especially if there be extensive effusion. In some instances of severe fractures of the ribs, when the chest has been much crushed, I have known the air extend as low as the wrist and ankles, and up the neck to the face and margin of the scalp, causing enormous swelling. Usually, however, in ordinary fracture, if there is emphysema, it is to a trifling extent. Perhaps the best treatment is to apply a pad over the seat of injury, and to retain it by means of the flannel roller, put on as in the common case. The abstraction of ten or fifteen ounces of blood will seldom be amiss; but should it happen that the difficulty of breathing increases, and the resonance of the chest is at the same time greater, the bandage must be removed, and cannot again be applied until the lapse of two or three days. At this time the wound in the lung will have healed,—the open cells will
at all events have been closed by lymph, — the air will probably have diminished in quantity, and soon the chest may be enveloped again. Emphysema in itself cannot be considered a serious condition; it indicates, however, a severe and even dangerous injury of the chest, and on that account the case must be treated with great circumspection. In extensive diffusion of air immediately under the skin, it might be advisable in some instances to make punctures with a lancet, though this need seldom be resorted to. If the case does well otherwise, the air will ultimately (i.e. in the course of three, five, or eight days) entirely disappear. It is customary in such cases to say that it has been absorbed; but from what we know of its injurious effects in the circulation, it seems, with me, difficult to imagine that it all goes off in this way, and I am inclined to suppose that there must be a process of cutaneous exudation as well.

If the dorsal portion of the spinal column has been fractured, or two of the vertebrae have been separated from each other, the injury is almost as hopeless as those in the cervical region, already referred to. Such accidents must invariably be accompanied with serious lesion of the spinal marrow, and the aid of surgery will seldom, if ever, prove of any avail. The patient will be paralyzed below the seat of injury, and though, perhaps, perfectly sensible, and able to use his arms freely, he will have little or no power over the muscles below; the integuments will be insensible to touch; the sphincter ani will have little or no power; the bladder will be paralyzed, with consequent retention; the urine will become ammoniacal; and often there may be continued priapism. The state of the bladder will render the catheter necessary at regular intervals (perhaps twice or three times a day); and as the patient will always rest in the position in which his body is placed for the time, and moreover will require great attention as to cleanliness, all care must be taken by means of pillows, and attention to the bed-clothes, to prevent injurious pressure on certain points, and to keep the skin as dry as circumstances will permit.

Extension has been applied to the column in some of these cases, and an interesting successful case of the kind has been related by Mr. W. H. Crowfoot, in the eleventh volume of the Transactions of the Provincial Medical and Surgical Association. Pressure has been laid upon the gibbous point by way of forcing the protrusion at the back (which is often conspicuous) into its proper position. The wooden bed (scammum) of Hippocrates has been used for the purpose, and Oribasius alludes to such practice. No harm, in my opinion, can accrue from a moderate attempt at extension, although its ultimate utility may be doubted; but the idea of forcing the protrusion into a proper position seems preposterous.

Mr. Henry Cline proposed to remove one or more of the laminae in these cases; but neither the example in which he did so, nor several treated in the same way by Mr. Tyrrell and others, did well. The analogy between such injuries and those of the head when there is depression of bone, though in some respects close, is widely different in others; thus there may be extensive depression on one side of the
cranium without any such condition on the other; but in the spine, when the column is broken, the irregularity will probably be as much on one side of the canal as on the other, consequently, pressure on the spinal cord may be just as great and as destructive in front as behind. However, it is possible to imagine an instance where a lamina is driven in without the body of the vertebra being affected, and, as the case may be in any way almost hopeless, it might be deemed advisable to give the patient the advantage of this poor chance. This subject was revived a few years ago (1865) by Dr. Macdonnell, of Dublin, who reported an operation of the kind performed by Dr. Gordon, of the Whitworth Hospital, and read a paper on it to the Medico-Chirurgical Society of London, which was published in the Transactions for 1866.

In dissecting the muscles of the back, it will be perceived that there cannot possibly be any difficulty in dividing, by subcutaneous incision, almost any which the anatomist may desire to reach. Some years ago it was proposed to divide one or all of these on one side of the spinal column in cases of lateral curvature. M. Guerin was the most zealous advocate for this practice, and it has been performed by him and others, in a variety of instances, on the supposition that there is an analogy between this condition and that of club-foot. I have had no experience of such a method of treatment, and from all I have seen on the dead and living body, feel strongly prejudiced against it as a general practice. The more rational mode of endeavouring to improve the vigour of the patient's frame (supposing her to be a miss of nine, twelve, or fifteen years of age) by local friction, change of air, habits, and diet, and also of giving the spine an opportunity of resuming its natural symmetry and elasticity by taking off the weight from above,—which can only be properly done whilst the body is in a horizontal posture,—seems to me infinitely to be preferred to the method alluded to.

Occasionally the surgeon is required to make an opening through the walls of the chest to permit the escape of fluid. This is sometimes deemed necessary in extensive accumulation in hydrothorax, at other times for empyema, where pus fills the greater part of the cavity of the pleura, or probably occupies only one portion of the side of the chest.

In hydrothorax, the operation (paracentesis thoracis, as it is called) may be done thus: The patient being placed on the margin of a bed or table, and leaning slightly over on the sound side, the surgeon should select the seventh or eighth rib a little in front of the angle, and should then draw the skin upwards, and bring what was formerly opposite the lower margin on a level with the upper; next with a scalpel, he should make an incision about half an inch long, through the skin, cellular texture, external and internal intercostals, until he nearly reaches the pleura, which he should penetrate by a small puncture with the point of the knife, or better with a trocar. Sometimes a trocar (and canula) is the only instrument used, but I think it best always to divide the skin with a knife, and then puncture with the trocar both intercostals and pleura. An
ordinary round instrument, such as that displayed a few pages further on, will answer for this proceeding, but a flat shape, as represented here (fig. 401), answers best for pushing between the ribs. When the fluid is evacuated, and the canula is withdrawn, the skin, being let go, will slip over the internal orifice like a valve, and thus there is less chance of air getting into the cavity than if the wound were made straight into the chest. If the operation is performed higher up than is here recommended, some of the fibres of the serratus magnus will come in the way, but no harm can accrue from their division. It will be remarked that, by keeping on the upper margin of the bone immediately below, whilst cutting between the ribs, there is no danger of interfering with the intercostal artery.

If the operation is done for empyema, the proceedings may be nearly of the same character. The same situation may be selected, or any other more convenient spot. Sometimes in such cases the matter causes more marked protrusion between certain ribs than elsewhere, and such a point may be selected. I once operated in a case of the kind between the first and second rib; but here the disease was more like abscess in the upper region of the chest, for, in consequence of adhesions, the matter was limited to this part. In this instance I passed a bistoury straight into the sac, having pulled the skin slightly upwards—letting the matter flow without using a canula; and a similar mode will answer either for this affection or a hydrothorax, but I prefer the method described above.

In all instances it is very desirable to perform these operations without permitting air to enter the chest. In hydrothorax this may be accomplished, but in empyema it will be found exceedingly difficult. In the former example the lung will probably expand as the fluid escapes, but in the latter this is very doubtful, for often the surface of the pleura pulmonalis is so coated with adventitious layer of organized lymph as to prevent the lung rising at once, if, indeed, it ever will do so. In such a case it has been proposed to operate on the patient whilst he lies in a bath, or to use a syringe to exhaust the matter, and at the same time, by creating a vacuum to give the best possible chance for the lung to rise. Should this happen, it will probably not be to the full extent, and in the event of the patient surviving, the chest will ever after be smaller on that side than on the other. Whatever care may be taken to prevent the ingress of air, the occurrence is extremely likely to happen. I must say, however, from my own experience where this has happened, that I have not seen any evil follow directly therefrom.

Some practitioners are very particular on this point, and in modern times a caoutchoue tube has been adapted to the outer end of the
canula, with the purpose of letting the fluid escape into a vessel at such a
distance (perhaps on the floor) from the chest that air could not ascend.
The tube has a nozzle at one end, which can be accurately fixed into
the canula as the fluid escapes; but it is better, when this practice is
specially desired, to use apparatus similar to that recommended for
paracentesis abdominis, or for puncturing ovarian cysts, and referred
to a few pages further on. I have within these few years had con-
structed several flat instruments of the kind, intended specially for
operations for the extraction of fluids from the chest. In some
instances it may be deemed advantageous to extract part of the fluid
by means of a syringe. The walls do not contract, as in the abdomen
or tunica vaginalis, when the fluid escapes, and so a large quantity
may remain, particularly when the lung does not expand freely. I
have often extracted more than a quart of fluid after a spontaneous
stream had ceased, with great apparent advantage.

The bleeding during the performance of any of these operations will
be very trifling. The only vessel of magnitude in such parts being
the intercostal, which may be avoided by the instructions given.
Occasionally an artery about the size of an intercostal passes from the
subclavian in a direction downwards, between the ribs and pleura,
exact, in the line of the incisions described.

When suppuration occurs near the ribs, cartilages, or sternum, it is
not unusual for caries to be the result—perhaps in the cartilages the
condition is more like necrosis. Such abscesses are generally super-
ficial, but occasionally they form behind, and make their way to the
surface through a small opening, which greatly retards the discharge
of matter, and thus such abscesses become chronic and often very
painful, so that the sufferer can make little use of his intercostal
muscles, or even of his arm on the side affected. In some of these in-
stances I have clipped away portions of both cartilage and rib with
excellent effect. But the practice is not without hazard, owing to the
vicinity of the pleura, or (if the disease be about the cartilages of the
lower ribs) peritoneum.

Portions of the sternum and ribs have been removed in consequence
of caries, but no particular rules are here required for such proceed-
ings. In caries or necrosis of the sternum a crucial incision will enable
the surgeon to apply the gouge with the desired effect. Large portions
of this bone may be thus removed: but there is scarcely any necessity
for doing more than allude to the important parts in the vicinity—the
pericardium behind, the pleura and internal mammary artery at the
sides, and the large vessels at the upper part of the anterior media-
stinum, are all dangers so palpable, that the smallest amount of ana-
tomical knowledge will point them out. Portions of ribs have been
removed in many instances, for caries, necrosis, or tumours, and with
excellent success. Generally, these proceedings have been accom-
plished without injury to the pleura, but this membrane has, in some
of these cases, been accidentally opened; yet the patients have done
well. A case of the kind is referred to in the London and Edinburgh
Monthly Journal of Medical Science, for August, 1842. M. Jacquet,
in removing enlarged and carious portions of two of the ribs (succeeding to fractures of these bones, occasioned by a blow five-and-thirty years before), opened the pleura, yet, in reading a paper on the subject before the Society of Natural and Medical Sciences of Brussels, he exhibited the patient perfectly cured.

Dislocations are of rare occurrence in the pelvis, and can only happen under extreme violence, which will at the same time produce fracture. The latter is an injury which is occasionally met with, and is usually so severe in character that death often results, either within a few days from the effects upon the pelvic or abdominal viscera, or at a later period, in consequence of suppuration in and around the fissures.

When any portion of the pelvis is fractured, the violence is commonly so great, that other organs suffer seriously besides the bones, and, formidable though the fracture may be, it will perhaps not be the most important feature of the injury: thus the bladder, peritoneum, part of the intestinal tube, or other abdominal viscera, may be ruptured,—perhaps the spine may be broken,—a thigh-bone,—indeed, such cases are often complicated in the manner alluded to. The fissures may run in almost any direction: above the acetabulum they can generally be detected by external examination, and by seizing the crest of the ilium: below—in the pelvic portion, if external examination or some force to the tuberosity of the ischium does not indicate the seat of fracture, the finger passed into the rectum will usually do so, especially if it be in the ramus, in the eoeexy, or lower end of the sacrum.

The treatment in cases of this kind is to attend to the condition of the viscera within, in such a manner as the principles of surgery indicate: thus, if severe inflammation ensues, leeches, cupping, warm fomentations, and such other measures as are usually employed to arrest that process should be resorted to: again, should the bladder or urethra (as might happen) be ruptured, the propriety of introducing a catheter, and retaining it, cannot be doubted; then, to keep the parts as still as possible, the pelvis should (at first, or as soon after topical blood-letting as is convenient) be enveloped in a flannel roller. Sometimes a long splint, such as that described at p. 355, sufficiently long to reach the chest, may be of service. It is scarcely necessary, after all that has already been stated about fractures elsewhere, to point out the necessity for keeping the patient's body as still as circumstances will permit.

Incisions are required for various purposes in and about the abdomen and pelvis. The young surgeon will probably be called upon at an early period of practice to make an opening into the peritoneal cavity to permit the escape of fluid in ascites. The operation (paracentesis abdominis) may be done in the following manner: The patient should be seated on a chair or the margin of a bed, and the upper part of the abdomen should be encircled with a folded table-cloth or sheet, the middle of which should be laid over the stomach, and the two ends being made to cross each other behind, should be given each to an assistant, who should be directed to pull them with moderate
tightness, by which the tenseness of the parts below will be increased. Then the surgeon, resting on one knee, or seated on a low chair, should pass a trocar and canula through the linea alba about an inch and a half below the umbilicus, so as to penetrate the abdominal cavity; this being accomplished, he should withdraw the trocar, allow the fluid to pass through the canula into a bowl held in the hand, or a pail between the patient's feet, and when it has entirely escaped, he should close the wound with some adhesive strap, place a folded towel on the part, bring the sheet down upon it, and after carrying the loose ends in front, fasten them by pins, or with a needle and thread. It is usually considered that as the fluid escapes, and the pressure on the vena cava becomes less, there is a probability of the patient fainting, and hence the necessity of always keeping up pressure by gradually tightening the cloth encircling the body, and afterwards keeping it fastened for a time, until the parts become accustomed to their new condition. Instead of having the patient seated, it answers very well to let him lie in bed, with the abdomen projecting over the margin. There is thus less fatigue, and less chance of fainting, and I almost invariably operate in this way, without using a binder, until the wound has been dressed. This was an old method of operating, which had fallen into abeyance. For five-and-twenty years I have rarely put the patient into any other attitude. I adopted it first at the suggestion (I think) of Dr. Todd, in operating on a patient under his charge; and it is now very generally preferred. Sir James Simpson adopted this plan, I believe, and it was that usually selected by Mr. J. B. Brown, at St. Mary's Hospital.

In using the trocar in the above proceeding, some considerable force is required—a kind of plunge,—and it is well to guard against the point passing too deep, by keeping the forefinger within half an inch or so of it, as represented in the drawing (fig. 402). If the instrum-
th point of the knife into the peritoneal or cystic cavity, and then introduce the trocar and canula with the least imaginable force. Such an instrument as that represented in figure 401, answers very well for this proceeding.

This is an operation which must probably be repeated very frequently on the same individual, and in future punctures the cicatrix of the preceding one may be selected, or, what will be better, the instrument may be passed a little higher or lower, at the will of the operator. If he goes above the umbilicus, however, he must remember the proximity of the liver, which in such cases is often much enlarged; and if he makes the wound nearer the pubes, he must be certain that the bladder is not over-distended. It is occasionally the custom to make the puncture in the linea semilunaris, about midway between the anterior spine of the ilium and the umbilicus; but when this part is selected, it is usually in cases of ovarian dropsy, where the projection is often more prominent on one side than the other. The proceeding in either place, and in either disease, is so much alike, that I need not refer particularly to the latter. The orifice usually heals by the first intention, but sometimes the serum collects so rapidly again, that it bursts forth within a few hours, and continues to run for some days, until the wound closes by granulation.

Since the last edition of this work was published, a vast addition to operative, and, happily, curative surgery, has been added to our legitimate practice. The operation of ovariotomy is now so thoroughly recognised as a valuable means of saving life and affording relief and comfort, that it can no longer be passed without notice, or held up to scorn in a work professing to treat of ordinary surgery. It is but scanty justice to the memory of John Lizards to name him as the originator of the operation in this country. His proceedings were adversely commented on, and opposed as vigorously as if he had been another Jacques or Paré. But a great change has come in modern times, and even such mistakes as he committed, incidental as they were to a new subject, and held as fatal to his proposals, have been far surpassed, without, however, seriously retarding the onward successful career of this now highly valuable proceeding.

The subject of Ovarian disease—its nature and treatment by operation or otherwise—has been extensively considered in modern times; and there is perhaps no speciality which has been more successfully and practically worked out by the present race of practitioners. The writings of Clay, Bird, I. B. Brown, Walne, Spencer Wells, Keith, Bryant, and others, bear ample testimony to these statements, and they also render it less needful that I should dwell long on the subject in a work of this kind.

Disease of the ovary, in whatever shape, is almost certainly fatal if left to itself, or even under palliative treatment. If there is fluid, whether in a single cyst, or in several, tapping affords temporary relief, and in many instances years of comparative comfort may thereby be gained. Death, however, sometimes results from the operation; and in many cases, as the fluid accumulates after each tapping, it may
be a question if more rapid exhaustion than would befall by letting alone has not really been the result of interference. The few examples of cure after one or more tapings are so rare that they ought not to influence the prognosis; and the comparatively few instances of successful results from injections, such as of solutions of iodine, may be referred to in similar language. Our knowledge is so far precise that whenever a clear diagnosis of this disease can be made, the line of practice is as well defined as in tumours within the scrotum. The usual measures for inducing absorption will have been tried, or may now be; but soon it will be a question whether such means are to be further pursued, or another course taken. It may be decided to let alone altogether; but the disease, most characterized by swelling, will almost certainly increase, and by its weight, size, and pressure, particularly as regards respiration, necessitate some process of surgery. Now it must be decided whether relief is to be given by tapping, or that ovariotomy shall be performed. The trocar and canula will almost invariably be chosen as a first step. In some instances the entire removal may at once be selected. The decision will often be influenced by the seeming character of the disease. If it be a solid mass, tapping is out of the question, and ovariotomy, or let alone, must be the decision. Even when the tumour is clearly cystic, its removal may at once be proposed, but the step is comparatively so hazardous that most practitioners recommend the milder practice of tapping, for once or twice at any rate. The experience of Mr. Spencer Wells has led him to inculcate this doctrine. The operation may be done much in the manner described in previous pages for paracentesis abdominis. In asetites there is only one cyst, the peritoneum, therefore only one puncture required; but in the ovarian tumours there may be two or more cysts; and here it will be best to tap each through the single aperture in the linea alba. It is needful in such cases to be careful how the point of the trocar is directed.

Supposing that ovariotomy is to be done, it may be performed thus: The patient being placed on a table or bed of convenient height, in a good light, and under chloroform, the surgeon, standing on the right side, should make an incision, between four and six inches in length, directly over the linea alba, commencing half an inch or more below the umbilicus; the skin, fat, and cellular tissue may be divided freely; often, however, there is great tenuity in all these tissues from distension; any how, on reaching the fibres of the linea alba the knife must be cautiously applied. It may even be thought best to divide the tissues on a director. Some nice discrimination is required to make certain when the peritoneum is opened. If there be adhesions between this membrane and the tumour, even an experienced pathologist may be puzzled; but if there be none there is generally some fluid in the peritoneum, which, by its escape through a small opening made with the knife, indicates that the serous surface has been reached. Through this opening a director may be slid upwards and downwards so as to permit a knife, sharp or blunt at the point as the surgeon chooses, to enlarge to the desired extent. Three or four inches will
usually suffice. Through such an opening the character of the tumour can readily be distinguished, and if it be needful to break down adhesions it will admit the introduction of the fingers or hand for that purpose. As the tumour contains fluid in by far the majority of cases, it should now be punctured where it is clearly seen through the wound: this may be done with the point of the knife, and the fluid (usually of dark grey or brownish colour, of the consistence of gruel), may be caught in dishes or allowed to flow in any direction. It is better, however, to use a large trocar and canula made specially for the purpose, with a tube attached, through which the fluid may flow into a dish on the floor. As the fluid escapes the cyst diminishes in size, and by gentle traction it may be gradually withdrawn through the opening in the linea alba. Often there is a difficulty in this process; there may be still too much fluid, or there may be a solid part of tumour. A little pressure will squeeze out fluid, but it may be needful to enlarge the opening if the hard mass be too big to pass outwards. This, however, is a rare circumstance. When all is out the broad ligament may be recognised, with the neck or pedicle of the tumour attached to it; or it may itself seem to constitute this part. The pedicle must now be firmly encircled, by means referred to a little further on, then cut through on the side nearest the tumour, which may now be lifted away. All fluid and blood must now be carefully sponged from the peritoneal cavity. If adhesions have been broken down with the fingers or divided with the knife or scissors, possibly some vessels, although small, may require ligatures or torsion, or to be touched with the cautery or some astringent. If ligatures are used fine silk should be the material, and both ends should be cut off, with the view that the noose and knot may remain ever after. The wound in the walls of the abdomen may now be closed by the interrupted, quilled, or harelip suture, at the fancy of the surgeon; and whichever kind is used, it is thought best to include the whole thickness from skin to peritoneum in the thread or wire. At this time the operator will not fail to perceive how thick the walls have become, and how short the wound is, as compared with their state in the early stage of the operation, owing to rapid contraction after the absence of the tumour. In thickness the change may be from a quarter of an inch to three-quarters, and in length from eight inches to four.

At one time it was thought needful in dealing with large tumours to make an incision nearly from the pubes to the ensiform cartilage, but experience has taught that by letting away the fluid as above described the flaccid cyst can be extracted through a comparatively small opening. If the growth happens to be solid, then it will probably be needful to make a longer wound than the few inches above indicated, and there is no objection to enlarging upwards as far as the linea alba extends. It is deemed unwise to cut towards the pubes. The bladder is in danger in this direction; so much so that it is at all times needful to empty it immediately before the operation. I have known it, in a case of solid tumour, where perhaps there had been adhesions, cut through in front and behind ere the surgeon reached the mass. The
contest between the long and short incision has ended in victory for the latter. There has been much controversy as to the best manner of dealing with the pedicle, so as to restrain hemorrhage after its division. At first a strong ligature was used, its end or ends being brought out at the lower part of the wound. Various disadvantages (positive or supposed) attended this method, and an instrument called a clamp (fig. 404), was substituted. With the ligature, the noose and both ends of the pedicle were left in the abdomen. With the clamp, the instrument and the distal end of the pedicle were kept outside the skin, and the part beyond and between the blades sloughed. The clamp was by many thought coarse and clumsy, and the thread was then used in modified ways; the noose and ends being kept out of the wound, or sometimes the two ends were cut off, and then it was allowed to remain within. The actual cautery has been used pretty freely, and very successfully too, for the division and scarring of the end of the pedicle; and to this day much variety of opinion remains as to the superiority of one or other of these methods, and others less worthy of note. Dr. Tyler Smith has had great success in removing the ends of the ligature and leaving the remainder in the abdomen; and Mr. I. Baker Brown has had even more marked success with the cautery. Mr. Spencer Wells has given trial to both these plans, but on the whole seems to prefer the clamp. For my own part, having seen all methods used, I am of opinion that more stress has been laid on any individual plan than has been warranted by experience; for whilst there are seeming advantages in each, there are palpable defects in all. The use of one or another is of less moment as to the result than many appear to imagine.

The trocar and canula used in these operations is an ingenious device, for which we are chiefly indebted to Mr. Spencer Wells. It is from half an inch to three-quarters in diameter. That part called the trocar, which in ordinary instruments is solid, is a tube. Its point, unlike the three or four-sided wedge of the common instrument, is sloped away like a two-sided wedge, the slope being all on one side. This trocar is longer than the canula. The latter is about three or four inches long; the trocar is a couple of inches or more longer. It so slides in the canula that its sloping point can be made to project beyond the canula as it enters the cyst and be withdrawn, for safety, whilst part of the instrument is within the cavity. The back part, or handle, of the trocar may be about an inch and a half behind the canula. It is rough near its extreme end for the adaptation of a caoutchouc tube, and by a simple contrivance the two metal tubes can at pleasure be fixed as one, or loosened for the play of one within the other. This figure (403) gives some illustration of the above descrip-
tion. The tubes may be made of German silver or of iron, plated; the point of the trocar or inner tube must be of steel. The instrument referred to at page 620, for withdrawing fluids from the chest, is a modification of this. A pair of hooks attached to the sides are sometimes added, wherewith the ovarian cyst is clutched, but they seem to me of little value.

The clamp at first used was the ordinary callipers of the cabinet-maker, and the instrument now generally in the hands of ovariotomists is one of the modifications, for the application of which to ovariotomy we are indebted to Mr. S. Wells. When the two blades nearest the hinge (fig. 404), are squeezed upon the pedicle and fixed by a screw, the handles can be detached, so that they shall not lie heavily and awkwardly in the way near the wound.

In this operation—or, as it might be called at present, department of surgery—there are, as in other proceedings, many little points to be attended to, such as can readily be appreciated by those versed in surgery otherwise; and those who wish more precise information must look for it in works specially devoted to the subject.

Besides punctures and incisions for abscesses and removal of tumours in these regions, which require no special comment here, the surgeon may occasionally display his skill by removing dead portions of bone connected with the pelvis. Necrosis is by no means unusual, associated with abscess and sinus about the os innominatum. I have frequently removed considerable portions of the crest of the ilium, and even of the tuberosity of the ischium. Some cases of the kind treated by me at King's College Hospital were detailed in the first volume of the Lancet for 1852. On one occasion I removed a portion of the lower end of the sacrum, and succeeded in curing various fistulous openings which resulted from several operations (five, I believe) previously performed by a surgeon who supposed he was dealing with an ordinary fistula in ano. No set rules different from those which belong to ordinary surgery need be given for these operations. The surgeon's anatomical knowledge will guide him as to the line and extent of the incisions which may be needed in such cases.

The congenital disease termed spina bifida, a pouch from the fibrous sheath of the spinal marrow or cauda equina, usually covered only by
thin skins, is one over which the surgeon has little or no control. Although not so fatal a malady as hydrocephalus, it is as little under restraint. No single plan of treatment seems applicable to the generality of cases—medicines are of no avail, local applications are equally useless; the tumour in the loins, or over the sacrum remains, and the little operation of puncturing, which requires no special description here, seems, though occasionally successful, of no greater value, whilst it in some degree causes danger. When such a method of treating this disease is adopted, the aperture may be made with a large sewing-needle, or (as will be best) such an instrument as that recommended (p. 468) for the puncture in hydrocephalus.

Ligature of the external iliac artery may be effected on any part of that vessel. Usually its lower third is selected, unless the surgeon is obliged to reach the vessel higher up. The operation may be performed in the following manner: The patient being laid on a table, with his shoulders and knee slightly elevated, an incision about three inches and a half long (marked a on fig. 405), should be made, about an inch above, and parallel with Poupart's ligament, one end being opposite the anterior superior spinous process of the ilium, the other a little above the opening in the tendon of the external oblique: the skin, fascia, and superficial epigastric vessels being divided, the tendon just named should then be cut to a similar extent,—this being usually accomplished upon a director pushed under the texture through a small opening cautiously made, although there is no great occasion for such an instrument: now the lower margins of the internal oblique and transversalis must be looked for, and the point of the finger (or that of the director) being passed beneath them, they should be divided about an inch upwards and outwards, when the fascia transversalis will be exposed, almost exactly over the internal abdominal ring; a slight scratch with the nail or point of the knife will make an opening here, which may be extended by a kind of laceration so as to permit a view of the iliac fascia where it covers the psoas muscle, when the artery will be discovered on the soft brim of the pelvis, covered by a thin layer of cellular tissue, forming a kind of sheath for it and the vein, and having perhaps a small twig of nerve in front of it. The vein lies close upon the inner side of the artery, and it will

---

Fig. 405.
be best, after making a slight opening in the sheath, to insinuate the point of the needle from within outwards, so as to avoid it: care may be taken, too, lest any other vein be in the way, such as the epigastric or circumflex,—the latter of which has been seen lying directly in front of the artery; the thread being fastened in the usual way, and the wound closed with a couple of stitches and straps, the operation is completed.

If the opening in the fascia transversalis is made close upon Poupart's ligament, the peritoneum will scarcely be disturbed. There is some advantage in this; but, on the other hand, the epigastric artery may be in the way—it has, in fact, been wounded in such a case,—and besides, by securing the artery so very low down, the proximity of the retrograde current of blood through this vessel might possibly prevent the closure of the main artery: it will, therefore, be better even to disturb the peritoneum by stripping it off the vessel somewhat higher, and there need be the less hesitation about this, as experience has shown that little additional danger is occasioned thereby.

The proceedings above described resemble in most respects those recommended by Sir Astley Cooper, but the external incisions may be, if it is thought proper, carried more parallel with the course of the artery, as practised by Abernethy in his first operation. The peritoneum is, however, in greater danger in the latter method, and most authorities seem to prefer keeping rather towards the crest of the ilium, so as to avoid the risk of opening the serous cavity; for, although the latter has actually been done with impunity (as happened to Mr. Tait), there can be no doubt of the propriety of carefully protecting the membrane.

Since 1796, when Abernethy first secured this vessel, the operation has been very frequently performed, and with such success, that the surgeon may undertake it with far greater confidence of a fortunate issue than in similar operations on other large arteries.

It may be necessary to apply the ligature higher up than has been recommended; and the only additional instructions required here for such an instance are, that the wound through the skin and other tissues should be placed an inch or so higher, and that the peritoneum must be more extensively stripped from the vessel, which lies somewhat deeper than at the lower third of its course.

Since 1812, when Mr. Stevens of Santa Cruz first happily tied the internal iliac for supposed aneurism of the glutaeal artery, the operation has been repeated in at least five different instances—in four of them with a fortunate issue, so that it has been successful in five examples out of six. The proceeding may be accomplished through the incisions last recommended, only it will be necessary to interfere with the peritoneum still higher, and possibly it may be requisite to make a freer external wound. Half an inch or more of the vessel can thus be exposed, and with care the needle may be carried round it without danger to the vein, which lies behind and above.

In 1827, Mott successfully applied a ligature to the common iliac artery for aneurism in the inguinal region. The operation had been
performed once previously by Gibson in a case of gun-shot injury; but the patient died on the sixteenth day after. It has since been done by Crampton, Syme, Guthrie, Salomon, Peace, Stanley, and other surgeons, with a degree of success sufficient to warrant repetition in future instances, and may be accomplished in the following manner:—A wound in the skin, from six to eight inches in length, should be made almost parallel with the upper end of Poupart’s ligament, and about an inch and a half nearer the mesial line: its lower end being from two to three inches below the anterior superior spinous process of the ilium. The oblique and transversalis muscles, and transversalis fascia being divided to a similar extent, the peritoneum with the ureter must be stripped from the fascia iliaca towards the mesial line, and raised from the vessel to permit the point of the needle being carried round a little above its bifurcation.

In the operation on the upper end of the external iliac, on the internal, or in that last described, the fascia transversalis will be found of greater strength than at the internal abdominal ring, and will probably require a freer application of the knife than in the latter situation. The peritoneum will, in all likelihood, separate as readily from the fascia iliaca and the front of the psoas muscle as it does on the dead subject. Indeed, from the admirable description given by Sir Philip Crampton, it appears that the resemblance on the living body to the proceeding on the dead is greater than in most other operations on the large arteries; for, with the exception of the bleeding from the external wound and the muscular parietes (which will probably have ceased ere the deep parts are exposed, although possibly the superficial epigastric and branches of the circumflexa ili may require ligatures), there may, in reality, be nothing to obscure the view of the vessels. Sometimes, however, an aneurismal tumour may be so high as to bulge through the opening, and the peritoneum, with the bowels within it, may also do the same. Mott had great difficulties to contend with from both of these circumstances, but overcame them by making a very large external wound (eight inches) and holding the projecting parts aside by means of curved spatule and a wooden board three inches broad,—either or both of which being more convenient in the wound, perhaps even more safe, than the fingers of assistants. If the patient be very stout and fat, the trouble will doubtless be in proportion. In an operation of this kind in my own practice, I experienced great difficulty in finding the lower end of the external iliac. The patient was very bulky and fat, and the glands and other tissues close upon the vessels were so enlarged, hardened, and matted together, that I was obliged to give up the attempt to secure the artery at the point originally intended, and to seek it higher up, where, being free from surrounding disease, it was very readily secured.

Letter \(a\) on the preceding figure (405) marks the line of incision for the lower part of the external iliac, and \(b\) shows that for the upper end of this vessel, for the internal, or for the common.

Letter \(c\) in the drawing above referred to shows the course of the
incision which was made by Sir Astley Cooper when he placed a ligature on the abdominal aorta. After opening the peritoneum, dividing the linea alba an inch and a half above the umbilicus, and as much below, Sir Astley, by scratching with his nail at the root of the mesentery, was enabled to insulate the artery, and carry a thread round it. A similar operation has been performed by Mr. James, of Exeter; but both were unsuccessful; and more recently another attempt by Dr. Murray has been equally unfortunate. A fourth case has been recorded in the first volume of The Lancet for 1842-3, p. 334. The operation was done at Rio de Janeiro, by Dr. C. B. Monteiro, and the patient survived till the fifteenth day. Dr. Murray, instead of opening the peritoneal cavity, secured the vessel by reaching it behind the membrane, somewhat in the manner above recommended for ligature of the common iliac. Such a method is doubtless best in dogs, in whom the vessel is usually reached by an incision parallel with the outer margin of the quadratus lumborum muscle; but, in my opinion, a wound sufficiently long could not be made between the crest of the ilium and the twelfth rib on the human subject, and in such an incision as that for the common iliac the depth from the surface would be so great, that there would be vast difficulty in conveying the thread round the vessel. When Mott secured the common iliac, the distance of the artery from the external wound was "the whole length of the aneurismal needle;" it would therefore be considerably greater were such an attempt made on the aorta. This operation has been recently repeated by Dr. H. M. Watson in the Royal Infirmary of Edinburgh, but with a result similar to all its predecessors. I look upon the process as hopeless as deligation of the subclavian on the inner side of the scaleni, and experience seems to me more useful in warning us not to attempt a futile proceeding, than to repeat what has hitherto proved so fatal.

Since John Bell's celebrated case wherein he tied the gluteal artery, which had been cut across in a punctured wound, a similar proceeding has, I believe, been effected by Mr. Syme, although I have not heard that the operation was so formidable. Mr. Bell first made an incision through the skin and "great fascia of the hip" two inches and a half in length, into the large collection of effused blood; this not sufficing it was made "eight inches long;" then the patient being in danger of bleeding to death, although "in a moment twenty hands were about the tumour, and the bag was filled with sponges and cloths of all kinds," the intrepid operator "ran the bistoury upwards and downwards, and at once made an incision two feet in length," by which he was enabled to secure the open vessel. The patient ultimately recovered, although he was so exhausted from loss of blood, that he could not be removed from the operating theatre of the hospital for some time after.

For such operations no rules are required further than those inculcated in various parts of this volume, nor do I consider it necessary to occupy space by describing the ingenious dissecting-room proceedings whereby it has been proposed to carry a ligature round the
epigastric, ischiatic, or the common pudic artery, where it lies behind the spine of the ischium.

CHAPTER III.

HERNIA. OPERATIONS.

Few subjects in surgery have attracted more attention than that of hernia. In whatever condition this state is found, in infancy, manhood, or old age, it is full of interest, not only on account of its frequency, but because it is at all times fraught with imminent danger, which usually comes when it is least expected.

The anatomist is familiar with all the weak points in the parietes of the abdomen through which protrusions, constituting hernie, make their appearance. At the groins, in the inguinal and crural canals, at various parts in the pelvis, at the umbilicus, and at other parts, or where wounds, if neglected, are likely to be followed by protrusion, he can have no difficulty in appreciating the leading features in such cases. By far the most common are those at the inguinal and crural canals, and at the umbilicus, and the young surgeon usually gets the principal part of his information regarding them from his teacher in anatomy. It is hardly within the scope of this work, in its present condition, to point out all the peculiarities of such cases. In a work devoted to hernia alone this would be needful, but as in this volume the subject is joined with many others on which principles are chiefly intended to bear, I shall treat it much as I have done them.

Under ordinary circumstances the management in reducible hernia is principally confined to the patient and the truss-maker. The surgeon may sometimes, however, be consulted regarding certain tumours, whose nature may be doubtful; and though it seldom happens that he has much difficulty in the diagnosis, cases are occasionally met with which may require more than usual care in their examination. In some instances there is a want of caution evinced, and such hasty conclusions are drawn, that much anxiety on the part of patients and friends is frequently caused by those who form too hasty opinions. I have known a truss ordered by a practitioner for a boy about five years of age, where the testicle was presenting at the lower opening of the inguinal canal, and where there was no apparent disposition to protrusion of the bowels; and very recently an example has come under my notice where the testicle, in a somewhat similar case, had been completely wasted away by the continued pressure of a truss. Again, I have known the truss ordered and worn in instances of hydrocele and varicocele in the adult, and although in the first of these affections little harm might accrue therefrom—ex-
Hernia. Operations.

Excepting the anxiety of mind occasioned by the supposition that a rupture is present—it is generally supposed that the latter must in all probability be increased, although some modern surgeons have actually recommended the practice. The history and diagnosis of such diseases need no especial notice here, and the hernia in a state of strangulation may therefore at once be taken under consideration.

One of the most common tests of hernia is the presence of a tumour, although this cannot always be appreciated; but there are certain symptoms usually denoting the state of strangulation which can scarcely be overlooked: the pain in the abdomen—often of a gnawing, dragging kind,—nausea and vomiting, obstinate constipation, swelling of the bowels, thirst, feverishness, excited or perhaps small and wiry pulse, are all palpable symptoms of a strangulated hernia, especially if a tumour of the kind be present. If the surgeon has not been aware previously of the existence of such a disease, the symptoms should be sufficient to induce him to question the patient on the subject, and should he also be in ignorance on the subject, a strict examination of all the ordinary seats of such protrusions should be instituted. If a tumour be present, there will be pain in it from the first, which will probably extend from thence over the abdomen, and now the protrusion will be more tense than usual, and are long tender to the touch:—there may be inflammation on its surface as well as within. All the symptoms above enumerated may be present independent of hernia, or the tumour may be so very small as to be overlooked, or of a doubtful character: if, however, there be a distinct swelling in the ordinary site of this disease, there need be little hesitation about the cause of the patient's sufferings. I have met with an instance where the symptoms of strangulated hernia were very urgent, and when two practitioners were put off their guard in consequence of a large umbilical hernia remaining quite flaccid and painless. Examinations at the other seats of hernia had been neglected: there was a small crural hernia on the right side, on which an operation was soon after performed with success.

Supposing the case to be one of hernia in a state of strangulation, the first object with the surgeon should be, to return it into the abdomen by means of the taxis, as it is technically called, viz., applying his fingers, and pushing the parts into their natural position.

To accomplish this in inguinal hernia, the patient should be laid on his back, and a cushion placed under the shoulders, whilst the thigh is bent towards the abdomen; the surgeon should place his fingers on the tumour so as to raise it a little, if it be down as far as the scrotum, and at the same time to apply pressure upon a large extent of its surface: he should then push upwards, outwards, and towards the peritoneal cavity, and if the attempt is to be successful, the contents of the sac will diminish, at first in an almost imperceptible degree, but towards the end of the operation with great rapidity, and with a peculiar gurgling noise. To prevent a recurrence of the protrusion, a truss should be afterwards worn at all periods when the patient is in the erect posture, or employed in any
kind of exercise or labour. In many instances, when there is great tendency to protrusion it may even be advisable to keep the instrument on whilst in bed. If one has been worn for a long period, perhaps from infancy, and if the protrusion has never been large, it may probably be laid aside at last; but there may be danger in doing so, even though the original sac may have been completely obliterated by the long-continued pressure.

But it will often happen that the manœuvre above described cannot be accomplished at once, and therefore certain means must be resorted to in order to facilitate the process. Usually the first step in the treatment of such a case is to administer a purge by the mouth,—this being done chiefly to ascertain if the intestinal canal is really obstructed, and partly, also, under the idea that the excited action produced thereby in the muscular fibres of the intestine, may draw the protruded portion within the abdominal cavity again,—and either before or after a purgative clyster is also resorted to: then antispasmodics are given by the mouth and per anum, opium being administered in either way, or tobacco in the form of clysters and smoke, and a relaxing effect is further produced by the warm bath. Occasionally warmth itself is applied to the tumour, but more frequently cold is put upon it by means of ether or ice. Sometimes leeches are placed upon the swelling, and generally blood is abstracted by the lanceet, especially if the strangulation be very recent, and the patient young and robust. The taxis often succeeds after one or more of such measures have been adopted; but in many examples the efforts are unsuccessful, and the surgeon has to determine what is best to be done next. Still unwilling to put the patient to the hazard of a cutting operation, he may possibly repeat some of these accessory means. Purgatives, in my opinion, invariably add to the patient's distress, by increasing the already excited action in the intestines above the seat of stricture: large quantities of tepid water introduced into the intestines by a long flexible tube attached to the enema syringe, as recommended by Dr. O'Beirne, may be of greater service, although not much to be relied upon either. A repetition of opiates and antispasmodics will seldom do harm, and occasionally while the patient is under the influence of one or other of these, the worst symptoms will disappear, and the taxis may now be successful,—indeed, in some instances the swelling recedes spontaneously. It may often be a question how long such efforts shall be continued; and here the surgeon must be guided by a variety of circumstances, which his general professional knowledge will lead him to appreciate. If the patient be young and plethoric; the tumour small, hard, and tender; the abdomen tense and painful; the pulse small, quick, and hard; if there is incessant vomiting, and occasional hiccup; coldness of the extremities, great depression of strength, and general distress, there should be no more time lost in pursuing such methods, especially if any of them have been tried before; but if, on the other hand, the symptoms are not so urgent, they may be persisted in for hours or for days. In one instance strangulation may produce fatal effects, although re-
lieved within a few hours; in another, the condition may be present for many days, and yet permanent relief may be afforded by the taxis or by cutting. On one occasion a surgeon will at once feel convinced that the taxis will not succeed, while in other examples he may see no impropriety in continuing his trials in this way for half an hour, an hour, or more, with or without the adjuncts above alluded to. In hospital practice these preliminary measures have commonly been tried before the surgeon sees the case, and therefore he seldom delays so long as he otherwise might.

In the present day it seems to me that less reliance than ever is put upon the accessory means above referred to, and I cannot but express my approval of the change. I am now disposed to think that chloroform is the most potent assistant we possess, and if the patient be put under its influence, and the taxis does not succeed, then I imagine that the surgeon is hardly justified in trusting to any other means than by operation.

If, then, it is impossible to reduce the contents of the sac by the taxis, and the evil symptoms continue, the use of the knife becomes absolutely requisite; and in my opinion the sooner it is resorted to, when once the surgeon is satisfied that he cannot relieve the patient in any other way, so much the greater chance is there of success attending the operation. The instruments for this proceeding are, a scalpel, a director, and a curved probe-pointed bistoury, with other apparatus and assistants such as are usually required for capital operations. By way of illustration I shall suppose a case of inguinal hernia which has descended some way into the scrotum. Whatever be the size of the hernia, a wound through the skin of two or three inches in length will, in general, permit of the due performance of the future steps; if the tumour be small a shorter incision will scarcely suffice, and if large, a longer one will not facilitate the movements of the surgeon much, whilst it may increase the patient's danger considerably by the exposure of additional extent of textures. It may, however, be requisite to increase the length of the external opening in particular cases. The patient being on his back, with the knees (especially that on the affected side) and shoulders slightly elevated, the surgeon, standing between the legs or on whichever side is most convenient, makes an incision through the skin over the neck and body of the tumour, its upper extremity being nearly midway between the anterior superior spinous process of the ilium and the tuberosity of the pubes, about one inch and a half above the level of Poupart's ligament, and its lower about the middle part of the scrotum, as indicated in the accompanying drawing (fig. 406); the cellular membrane should next be divided in the same line, and to nearly the same extent, so as to lay bare the outer surface of the sac: a small aperture should be cautiously made in this membrane, which should then be more fully laid open with the probe-pointed bistoury; the apex of the forefinger of the left hand should now be passed upwards to the neck of the sac, and the bistoury laid flat upon it; the point of the latter should then be cautiously insinuated beneath the stricture, which must be divided
by turning the edge and pushing it upwards and forwards, so as to cut the anterior part of the neck of the sac, and all structures over it which seem to cause or assist in forming the stricture: the knife being withdrawn, the bowel is then to be pushed gently upwards until it recedes into the abdomen, when the wound must be stitched, and covered with a thick broad compress (a soft towel answers very well), which should be retained by means of a roller passed in the figure of 8 round the thigh and pelvis. The two hands and the bistoury are here (fig. 407) represented in the usual attitude on these occasions. The edge of the knife may be supposed to have been turned towards the stricture, and it will be evident that its point may be raised either with the right hand, or with the forefinger of the left.

It has been the custom of some teachers to recommend that the point of the bistoury should always be kept close upon that of the finger, and that the stricture should be divided by describing part of a circle with the right hand,—a manoeuvre which evidently could not be accomplished in a deep-seated stricture, as it often is, without making a much more extensive wound than the circumstances demand.

These instructions will give a general idea of the style and nature of the operation; but, to make the description more useful, it will be necessary to treat at greater length of the various steps, and also to refer to the ordinary appearances presented by each texture as it is exposed and divided.

If the hernia be of recent formation, the cellular tissue and fat will
differ little in appearance from the ordinary condition in their natural state; but if the protrusion has been of long standing, in all likelihood the structures between the skin and sac will be much attenuated. Towards the neck of the sac, however, the textures will resemble the natural condition of the abdominal parietes. After the division of the skin, it is customary to raise a little cellular tissue with the forceps, and to cut it by carrying the knife horizontally; a director is then passed into the little opening thus made, and pushed under a thin layer of cellular texture in the direction of the incision through the skin, and the part thus raised is divided by carrying the point of the knife along the groove of the director; by similar proceedings the subjacent structures are incised, until the sac is laid bare; in some instances the director being used perhaps only once or twice, and in others four or six times, according to the thickness of the parts or the boldness of the operator; a small aperture should then be made into the sac, by cutting cautiously with the point of the blade; or if there is any fear of passing so deep as to endanger the contents, the forceps and knife should be used and a director introduced as when the cellular texture has been divided in the previous steps of the operation: a probe-pointed bistoury, such as is here represented (fig. 408) should then be passed into the opening, and carried upwards and downwards, so as to expose the contents.

It is not easy in many instances to distinguish between the outside of the sac and the cellular texture over it; but in general there is no difficulty in perceiving when the sac is opened, partly by the escape of fluid effused from the serous surfaces, as well as by their comparative smoothness. In some the fluid is scarcely perceptible or in very small quantity, but in others it is to a considerable extent, particularly if the hernia is large, and has been for a long time in a state of strangulation. In the early stages it is of a clear or straw-colour, but in advanced cases it is commonly of a dark colour. The protruded parts are in general easily recognised, as much by their colour as the smoothness of their surface. In some few examples the colour is scarcely different from that of the natural condition, but in most it is of a dark brown, similar to that of chocolate. Occasionally the sac of an inguinal hernia is scarcely thicker, if at all, than the peritoneum in its usual state; but often it is like a stout fibrous bag.

In opening the sac, there is no occasion to carry the incision so high as its neck, nor so low as its fundus; if the tumour be small, this latter step can scarcely be avoided; but if it be large, the wound should never be carried so far, unless there be something peculiar in the case, such as the adhesion of part of the contents to the surface of the sac, when it may be advisable to use the knife freely.
If the hernia is of recent occurrence, and has protruded in the course of the cord, it may be requisite to pass the point of the finger a considerable way up the canal, before the seat of stricture can be ascertained; a portion of the tendon of the external oblique may even require to be slit up before the neck of the sac can be examined in a satisfactory manner; but if the disease has been of long standing, even if the descent has been through the whole canal, the upper or inner opening (in the fascia transversalis) is in general not far distant from that in the tendon of the external oblique, having by a gradual process passed downwards (or been in a manner dragged by the weight of the protruded viscera) until it has come nearly opposite the latter part, so as to have made the passage from the sac into the abdomen nearly direct, and diminished the length of the canal, if it can now be called so, to merely the thickness of the abdominal parietes in this situation. In the first of these instances, when the hernia takes an oblique course, the division of the tendon of the external oblique to a small extent may permit the return of the protruded parts: it may be necessary, however, to cut deeper, and divide the lower margins of the internal oblique and transversalis muscles, or the conjoined tendons, or perhaps the neck of the sac, with a portion of the fascia transversalis; and in the instance where the upper extremity of the canal has come down opposite the lower, the whole of the structures will, in all likelihood, assist more or less in forming the stricture—at all events, in cutting it, a small portion of each of them will probably be divided. At this step of the operation the bistoury should be nearly in a parallel direction with the linea alba, and the upper margin of the opening should be the seat of division. The epigastric artery will be either on the inner side of the neck of the sac or on the outer, as the case happens to be an oblique hernia or a direct one; but as the surgeon can seldom be certain as to the nature of the case, it will be better on all occasions to follow the above directions, as this vessel will thus be less endangered than if the incision were carried outwards or inwards, under the supposition of the hernia being oblique or direct, as to which points the operator might find himself mistaken. In dividing the stricture, the point of the knife should be raised from the finger, or it may be gently pushed upwards and forwards by the latter until about one-eighth or one-fourth of an inch of the textures has been cut, when an attempt may be made to reduce the contents of the sac; a little pressure should be applied on a part of the bowel nearest the neck of the sac, and if it recedes, the remaining portion will be readily made to follow; if part of the contents of the bowel—even a small quantity of air—can be squeezed into the canal within, the reduction will be much facilitated. If any portion of the omentum be down, it must next be returned, by pushing in that part first which is nearest the abdomen.

If there are extensive adhesions it may be found impossible to reduce the protruded visceras, and in such a case all that the surgeon can do is to divide the stricture freely; if, however, the adhesions be slight, they may with propriety be destroyed, to permit reduction. In some instances it is proper practice to remove a portion of the omen-
tum when it has become much altered in shape, and perhaps irreducible: in such a case a ligature should be applied above the part about to be divided, one end of which should be left hanging out of the wound, after the upper portion of the omentum has been reduced: in other cases it may be advisable, in consequence of sloughing, or a disposition towards it, to leave the contents unreduced, after having cut the stricture.

If, unfortunately, the intestine is wounded during the operation, which occasionally happens, chiefly through rashness, carelessness, or awkwardness, then there is no better course of procedure than leaving the aperture at the mouth of the sac, and retaining it there by means of a stitch through the bowel and the latter part—care being taken to keep the orifice in such a position that the contents of the gut will have free egress through the wound, without passing into the peritoneal cavity. Should the patient survive, and if there is an artificial-anus, there will be plenty of time afterwards to consider what is best to be done, and whether Dupuytren's mode of practice may be resorted to.

It has not been my design in this work to dwell at great length on any individual operation; and though I have been more particular in describing that for hernia, with its difficulties and dangers, than with most others (of which I have treated, the reader must not suppose that the subject has been exhausted; on the contrary, I have confined my remarks to the leading characteristics of the disease and the operation, as they have presented themselves to me in my own practice and that of others. It is well known amongst practical surgeons, that in different instances of hernia, when the knife is required, appearances will present themselves which no former experience could have anticipated, and it is in such examples that the real difficulties are encountered: even allowing that these are productive of no embarrassment to the experienced surgeon, it must be admitted by all who have frequently performed this operation, that no language can sufficiently explain the different appearances which may from time to time be the cause of serious impediment. These remarks will be sufficiently appreciated by any one who has already had experience in such proceedings, and I shall only further refer to the difference in the anatomist's description of the inguinal canal and the surgeon's description of the operation: in the first, various textures are spoken of under different names, whilst in the latter a general direction is given to cut through every texture (without specifying each fascia) between the skin and the sac or its contents: the one style answers the purposes of the anatomist, the other is, or ought to be, the view which the surgeon should take of the operation: the tissues may be thick or thin, and may be divided with a few strokes of the knife, or by frequent applications, as has been clearly pointed out in the preceding pages.

If a femoral protrusion be small and of recent date, the textures covering it will resemble the natural condition;—there will be a considerable quantity of fat and cellular tissue to divide ere the sac is exposed; and if it be large and of considerable standing these tissues
may be found remarkably thin. In some instances of old date, when the tumour has never attained a great size, the sac is a quarter or even half an inch in thickness; but in general it differs little in this respect from the usual condition of the peritoneum.

During the taxis in this kind of hernia, which is properly effected by applying pressure with the fingers backwards, and slightly upwards, too much attention cannot be paid to the position of the thigh, which should be bent upwards on the pelvis, whilst the patient is in a horizontal position, with the chest elevated on a pillow. The muscular parieties of the abdomen, as well as Poupart's ligament, are thoroughly relaxed in the above position, and if the fingers be judiciously applied, every fair chance is thus given to this method of procedure. It often happens, however, that the surgeon does not deem himself warranted in applying much pressure with his fingers; indeed, in many instances, from previous experience, he can form a tolerably accurate idea as to the likelihood of his efforts being successful or otherwise as soon as he places his fingers on the protrusion, and when convinced that taxis will not succeed, he should proceed at once to divide the stricture with the knife. A single in-

*Fig. 409.*

cision about three inches in length, as exhibited by the dotted line in the accompanying drawing (fig. 409) will, in general, permit all the requisite steps to be performed with facility. If the tumour is of considerable size it may be made longer; but in such a case an incision of this kind | | , of this \ , or of this \ , (I often prefer the last,) will be better; two or three flaps can thus be raised, and the parts can then be more clearly
distinguished. After the integuments have been partially dissection from the tumour, it is not necessary to clear away each succeeding layer in the same manner,—a single line of division being all that is required. The dissection must be conducted much in the same manner as is described in the operation for inguinal hernia: whatever is the thickness of the coverings, they must all be divided: and when the sac is opened, the finger must be pushed up towards the seat of stricture; a probe-pointed bistoury must then be passed a little higher than this part, and its edge being turned against the stricture, an incision of about one-fourth of an inch will in general suffice to permit the reduction to be accomplished.

With regard to the seat of stricture in this kind of hernia, it will almost invariably be found in the crural ring itself. It is customary for some surgeons to speak of Gimbernat's ligament as being the seat of stricture; but, in my opinion, it is not more so than any other part of the ring; and the idea is quite erroneous, that because this structure happens to be cut to permit the protrusion to be reduced, it has been the sole cause of the stricture. I think there can be little doubt as to the propriety of dividing this ligament, to the extent already mentioned, in preference to any other structure, and the reasons may be stated in a few words: the knife cannot be carried outwards without endangering the common femoral vein, and it cannot be conveniently passed behind the protrusion, so as to open the back part of the ring, nor if it were could any texture be divided likely to relieve the tightness; if it be carried in front, Poupart's ligament may be cut with facility; but the parts will be thus rendered so weak that a protrusion will more likely happen afterwards in the cicatrix; there is thus, then, only another side of the ring left, and that is formed by Gimbernat's ligament, which seems to me by far the most eligible part for the enlargement. When the aperture is thus cut its diameter is increased, and the stricture is consequently removed.

In some instances the stricture may be relieved by dividing the upper horn of the crescentic margin of the fascia lata where it is attached to Poupart's ligament; it does not follow, however, that this part has consequently been the cause of constriction, for the effect of the incision has been to enlarge the ring, and thus to relax the real seat of stricture; nor do I suppose that the plan would answer in any instance where the latter is very tight: on some occasions, after having cut this part, I have not been able to push the bowel up, and have therefore passed the instrument a little deeper, and divided Gimbernat's ligament with the desired effect. It is undoubtedly easier to get at Poupart's ligament in this operation than at Gimbernat's; but the objection I have already stated to the division of this texture seems to me a good one; the edges of the ligament will never come close again, and there must be a certain relaxation of the parts afterwards; for however firm the cicatrix may be supposed to make them, it is certainly no unusual thing to see instances of protrusion occurring after the wound has completely closed. I do not conceive that, as some have supposed, there is any serious danger of injuring the spermatic
cord in cutting Poupart's ligament, as the knife ought never to be carried so high.

The slight additional difficulty of reaching Gimbernat's ligament ought not to deter the operator from dividing it in preference to the mode last referred to, and the only objection to this proceeding that I can perceive is, the risk of dividing the obturator artery, should it happen to originate from the epigastric, and run downwards to the obturator foramen along the inner side of the neck of the sac, parallel with the margin of the ligament. This risk has, I am inclined to think, been very much exaggerated, for although the irregularity is of common occurrence, as proved by the statistics of the dissecting-room, no average has been yet given of its presence simultaneously with hernia, nor would such a calculation be of any great practical value. In such a calculation it would be necessary to ascertain how often the artery runs on the inside of the neck of the sac, and how often on the outside; for it is by no means to be supposed that when the irregularity is present, and hernia occurs, it must of necessity pass on the inner side of the neck of the sac so as to be endangered in the division of the margin of Gimbernat's ligament. Even supposeing that the vessel is present in this unusual position, I believe that the ligament may be cut to the requisite extent without at the same time dividing the artery; and with this object the point of the bistoury should alone be passed beyond the margin; indeed, there is no advantage in passing the instrument deeper than is sufficient to allow its cutting edge to come in contact with the part to be divided, and if this be attended to, the obturator artery will in all probability escape, although it may even be in close contact with the neck of the sac and ligament of Gimbernat. At the worst, the accidental division of the vessel does not appear to be fatal in all instances, as one case at least (occurring in Dupuytren's hands) proves, wherein the vessel was wounded, and the occurrence was not even suspected until the death of the patient three weeks afterwards, from disease in the bowels, when a clot of blood in the site of the orifice led to the detection of the injury.

After the operation for crural hernia the edges of the wound should be brought into contact by stitches, and a pad retained over the parts by a bandage, as in the case of inguinal protrusion.

In relieving the stricture in either crural or inguinal hernia, the utmost care should be taken to avoid injuring the contents of the sac. I have known the point of the bistoury thrust into the bowel in attempting to pass it within the stricture, and in the crural protrusion there is considerable danger of committing this error, unless great caution be used. If the tumour is large, or if the stricture is deeply seated, the bowels are apt to turn up over the finger when, preparatory to dividing the stricture, the bistoury is on its anterior surface, and if the extent of cutting edge be great there is a risk of the intestine being wounded:—to avoid this, an instrument, such as the one here represented (fig. 410), where the cutting edge is of small extent, may be advantageously used. Some have even recommended
a bistoury with a sliding shield, by which the sharp margin may be diminished to the smallest possible extent. The bleeding from the external wounds in these operations (from the superficial epigastric, perhaps, or the external pudendal branches) seldom causes any annoyance, and ligatures are rarely necessary.

In the operations above described, the ordinary method of opening the sac has been recommended; but in large protrusions it would unquestionably be highly desirable to return the contents without thus exposing the peritoneal surface. In the majority of such cases, the stricture may be divided without penetrating the sac; but in some instances, even after this has been done, the protrusion cannot be returned in consequence of adhesions. If there were reason to suppose these of old standing,—as, for example, in an instance of long continued irreducible hernia,—it might be a question whether the contents should be exposed, but if the adhesions were supposed to be slight and of recent date, and, further, if it were deemed possible to succeed in dividing them, and then returning the viscera, or possibly taking away a portion of thickened omentum, the sac should be opened, but by a wound not larger than may be absolutely necessary to effect the objects in view. Even in small hernia, it has been proposed to relieve the stricture without opening the sac. The practice was resorted to by Petit and Monro, and in more modern times has received the sanction of Sir Astley Cooper, Mr. Key, Sir William Lawrence, Mr. Luke, and other surgeons of distinction. I have myself adopted it extensively, but cannot speak in unqualified terms as to its efficiency or eligibility in all instances. In many I have found it answer admirably, but in others, even after the stricture had been divided, I have, probably from an old and bad habit, felt that without opening the sac I could not be satisfied, and have therefore done so, occasionally with advantage, and never, that I could perceive, with any material difference of hazard to the patient; but I need not here dwell further upon this subject than to express my conviction, that the practice is worthy of far more consideration than it at present meets with from the generality of practitioners. The dressing of the wound and after-treatment should be the same whether the sac has been opened or not, and in all instances the patient, when again able to move about, must be enjoined to wear a truss as carefully as if an operation had not been performed. The cicatrix in these individuals gives no security against a second protrusion.

For many years I have rarely performed any other operation for crural hernia than that which has been recommended by Mr. Gay.
In a very able work "On Femoral Rupture," which that gentleman published in 1848, he recommended that instead of making the incision directly over the apex of such tumours, as is usually done, the knife should be carried along the inner side of the swelling near the tuberosity of the os pubis much as represented in the next figure (411). By such an opening in the skin the neck of the sac can be reached with far greater facility than in the ordinary way, the wound required for the needful steps of the operation is not so large as when made elsewhere, the bleeding is rarely so free, and the finger can be placed against Gimbernat's ligament with the greatest imaginable facility. Mr. Gay joins in the rising opinion that the sac need not be laid open as heretofore, and recommends the division of Gimbernat's ligament without interfering with it. Whether it be necessary to open the sac or not, I have much confidence in recommending this external incision as preferable, in the generality of cases, to all others. I have resorted to it in hernia of all sizes, from that reaching a third down the thigh, to that of the smallest imaginable bulk, and have invariably been fully satisfied. It may seem absurd and trifling to say so much upon the difference between an incision on the most prominent part of the tumour and one at the side, but if any surgeon in the habit of operating much in such cases, will try the method recommended by Mr. Gay, I feel assured that he will agree with me in considering that by such a simple difference a vast improvement has been effected in the operation for crural hernia. If the sac is not opened, such an operation is the nearest reasonable approach to the ordinary taxis that surgery has ever yet made.

For further valuable information, which every practical surgeon should possess, I must again refer to the works of Cooper and Lawrence, and the more recent and admirable treatise by the late Mr. Teale, of Leeds, regarding the kinds of hernia particularly alluded to above.
HERNIA. OPERATIONS.

The umbilical hernia is always easily distinguished from any other kind of tumour in this locality. It is by no means unusual to see hernial tumours here which are not exactly in the umbilicus. These protrude through a weak point in the linea alba. There is little (if any) practical distinction between the two. Perhaps the true umbilical hernia is most disposed to increase in size, and sometimes it attains an enormous magnitude. These protrusions, especially that at the navel, are most frequently met with in infancy, and by means of a pad and compress can usually be kept in check; so that ultimately, as the child gets older, the swelling no longer appears. In some instances, however, there is little tendency to improvement. It is usual in these cases to place a pad of cork or some elastic material over the opening, but I have often thought that an elastic bandage by itself, or even straps of adhesive plaster without any pad, answers better.

Should an operation with the knife be required in umbilical hernia, the proceeding by not opening the sac would doubtless be the safest, and here I should strongly advise an incision at one side of the neck of the tumour in accordance with the proceeding of Mr. Gay for femoral hernia above alluded to. I have found this method exceedingly simple in the operation for this kind of protrusion, and the margin of the opening through the linea alba can be so readily got at above, below, or at the side, that difficulty in dividing the stricture can scarcely be anticipated. An incision through the skin—which is here very thin—from an inch and a half to three inches in length, and a division of some part of the fibrous margin of the ring so as to permit reduction without opening the sac, will give the nearest step to the ordinary proceeding by taxis that can well be imagined.

The rarer kinds of hernia, such as the obturator, vesico-vaginal, recto-vaginal, perineal, diaphragmatic, or from wounds, or abnormal defects in the walls of the abdomen, need no special comments here, as a knowledge of anatomy and general surgery must lead to a rational appreciation of their nature and the treatment applicable.

The modern proposals by Gerdy, Guerin, Belmas, Bonnet, Velpeau, and others, of causing the obliteration of the sac or its neck, in cases where the contents are reducible, have as yet met with comparatively few advocates in this country; but the ingenious practice of Gerdy of turning in the sac of an inguinal hernia, as we might the finger of a glove, and using stitches to keep the part in this position, has met with most favour. Mr. Bransby Cooper succeeded in this way in partially relieving a person, who was disabled from active occupation in consequence of a large hernial protrusion through the inguinal canal, which could not be retained within the abdomen by any of the usual means. And of all it may be said that they are milder in character than the ancient plans with acids, threads, and gold wires, and seemingly less dangerous. Many years ago I saw a case treated at the Royal Free Hospital by Mr. Gay, where he opened the sac of a crural hernia, and removed a large portion of omentum which had become irreducible from adhesions, and the greater part of the sac at
the same time. The patient, a female, about forty years of age, made an excellent recovery, and by means of a truss was saved from further protrusion of bowel through the open neck of the sac. But unless there be some very urgent reason to meddle with a hernial sac in a quiescent condition, I imagine that the patient should, under the circumstances, be content with a well-fitting truss. Many years ago Professor Pancoast described the following radical measure. With a small trocar and canula, similar to figure 288 (p. 468), he makes a puncture, and injects half a drachm of Lugol's solution of iodine, or of tincture of cantharides, whereby obliteration of the sac is effected. In the operation care is taken that the contents are reduced before the puncture; when the point of the instrument is within the serous membrane some scratchs are made on the surface; the fluid is not permitted to pass within the peritoneum, first by the fingers which grasp the neck of the sac, and then by means of a truss which is worn for eight or ten days. The patient is confined to bed for the first week or so, and carefully watched lest inflammation of the peritoneum should ensue. Dr. Pancoast succeeded in thirteen instances where this method was tried, and in only one of them was there even a threatening of peritonitis: he was not able to declare the permanent results, as the patients usually went from under his notice after the lapse of the first few mouths, but so far as his opportunities of judging permitted, he had every reason to be satisfied, although in some examples, where the sac was very large, it had been necessary to repeat the injection. I am not aware that this practice has ever been tried in Britain.

Since the last edition of this work there has been considerable excitement on the subject of the radical cure of hernia in cases where strangulation has not been present, but when the patients have experienced annoyance from protrusion despite the use of a truss. The process of Gerdy was in great repute some years ago under the title of Wutzer's method; and Mr. Spencer Wells wrote in glowing terms of the success of that gentleman and others on the Continent who had practised it. The plan was largely tried in this country, and although found free of danger was soon given up, owing to the frequency with which protrusion appeared again. Various modifications were suggested, but out of a large amount of enthusiasm which at one time prevailed on the subject of radical cure, only one method seems to have survived and taken a place in surgery. The subject was proposed for the Jackson Prize at the College of Surgeons of England for 1861; and the award was in favour of Mr. John Wood, of King's College Hospital, who by means of incisions, needles, and wires, contrived so to agglomerate the sac and the margins or walls of the inguinal canal, that future protrusions rarely occurred. Mr. Wood's essay was published in 1863, and is well worth perusal by those who are specially interested in the subject. The operation in its chief features is as follows:—After inguinal hernia has been carefully reduced, a blade, like that used for tenotomy, is used to make an incision in the skin about an inch long over the
upper part of the serotum; its point is then carried between the skin and sae, so as to make a space, into which the point of the fore-finger can be freely introduced; a part or the whole of the sae is then pushed upwards by the point of the finger into the inguinal canal; a needle like this (fig. 412) is then passed along the finger,

Fig. 412.

and pushed through the sae and the outer or upper margin of the lower end of the canal, so that its point shall appear through the skin a little above; the end of a stout silver wire is then introduced through the eye of the needle, and bent acutely, so that it may be drawn through the track of the needle as the latter is withdrawn; the needle, freed from the wire, is then again to be introduced from below much as before, excepting that on this occasion it is made to pass through the inner or lower margin of the lower end of the canal, and its point made to appear through the orifice in the skin made by the first puncture; then the other end of the wire must be passed through the eye as the first was, and brought down to appear at the lower wound, where the other is; the two may now be drawn downwards, so as to bring the middle part of the wire into the orifice, and then by twisting they can be made so to contract and approximate the parts that the canal is firmly obstructed; or instead of letting the loop of wire sink under the skin, it is held in the fingers during the twisting, and then twisted itself by way of making the closure more perfect. Sometimes one end is carried a third time slightly across the track of the two, and brought out at the upper orifice, and then the closure of the sae is thought likely to be more complete. The long ends of the wire are cut off, and a pad of lint is put over the parts implicated, and the wire is left to be drawn out when inflammation, suppuration, and ulceration have thrown it loose. The adhesions thus produced are found so to obstruct and contract the canal that further protrusion rarely occurs, and even then it can be readily restrained by a more easy truss than may have been worn before. The patient has to lie in bed for ten days or more. The operation is not without danger both in its immediate performance and in its possible results, but it has been remarkably successful in Mr. Wood's hands; and I can write thus from extensive observation of cases treated by that gentleman. From all I know this seems to me the most efficient of the proposals hitherto made in modern times for the radical cure of irreducible hernia.

Some years ago I saw in London a gentleman of high standing and character in the United States, who had been radically cured of a reducible crural hernia. I afterwards met the surgeon who professed to practise this method of treatment, and was promised the knowledge
of it provided I permitted reference to my name, and bound myself to secrecy. I declined such a compact, but offered every other facility which either King's College Hospital or my own position could command. These proposals were not complied with, and I should scarcely have considered myself justified in such a work as this in taking notice of a professional matter of such importance, had I not been impressed with the idea that the surgeon in question was strictly honest, though imbued with an erroneous idea of the ordinary professional character in this country.

Some observations on opening the peritoneal cavity, and on gastrotomy, will be found in the next chapter.

CHAPTER IV.

DISEASES OF, AND OPERATIONS ON, THE RECTUM AND PERINEUM.

Few surgical diseases are better known among the public than those connected with the rectum and anus, yet there are few, perhaps, in which the surgeon generally shows to less advantage. The reason of this is that comparatively few such cases are seen in ordinary dispensary and hospital practice. The poor seem less afflicted with such maladies than those who are better off in worldly means, and hence cases of the kind are chiefly met with by the surgeon after his pupilage, when his knowledge is but small. Many such cases fall into the hands of those who are called "specialists," and among them the *genus* charlatan is frequently found. Anatomy and a general knowledge of surgery will prove as useful here as in other "special" ailments, and, with all respect for many good men engaged in this field of practice, I have no hesitation in stating my conviction that the best surgeon among them is likely to be the best in this as in other "special" departments.

In new-born infants, the opening at the lower part of the rectum may be so small that the meconium can be discharged only by drops: a collection above taking place, causing considerable protrusion in the perineum. With a probe-pointed bistoury three or four notches may be made, which will permit free evacuation.

An aperture may be required in the perineum in case of imperforate anus, and the proceedings may be simple or complicated according to circumstances.

It often happens, that the rectum is closed below by a thin portion of skin only. Here its projecting extremity, as the meconium collects, will soon become so distinct, that there need be no hesitation in passing the point of a knife through the obstruction, and thus giving vent to the contents. In such an instance a crucial incision will be advisable,
and it will be proper also to watch the healing of the wounds, lest the opening become too small. Bougies may be required from time to time.

In examples when the anus alone is imperforate, and where the gut immediately above is fully developed, the sphincter and levator muscles are, in all probability, entire, and the parts, shortly after operation, will appear as if nothing had ever been wrong.

But the bowel may be much deeper, and a firmer use of the knife may be required. Here the wound must be made in the usual site of the anus, and carried sufficiently deep to reach the end of the gut. This, however, cannot be accomplished in all instances, for the termination of the intestinal canal may be so high that it does not reach the cavity of the pelvis at all, or, if it does, the surgeon is reluctant to carry the instrument so deep in case of wounding the bladder, peritoneum, or iliac arteries. The latter vessels are closer to the wound than might be imagined, for in such young subjects, when the finger is passed deep, the sides of the pelvis can be readily felt—indeed, it is in close contact with them.

Occasionally the gut opens into the bladder or urethra, when, if its lower end cannot be reached, an incision must be made into one or other of these parts. A case of the kind once came under my own care, the particulars of which were published in the thirty-sixth volume of The Edinburgh Medical and Surgical Journal. An opening was made into the neck of the bladder as was supposed, and the operation was, in as far as circumstances would admit, perfectly successful. The boy lived and thrived till he was six years old, when he died of disease of the lungs. Although it may be doubtful if there was a sphincter or levator here originally, he had all the command over the aperture and the urinary apparatus that children usually possess. Occasionally, when his bowels were loose, a few drops of faces would come by the urethra, and he was wont also to discharge part of the urine by the artificial opening. On several occasions small hard urinary deposits were discharged from the anus, and I had to extract one about the size of a hazel-nut. Often his mother had to remove small seeds and barley-pickles from the orifice of the urethra, and once she extracted a small portion of bone which he had swallowed in his food. On inspecting the parts after death I found that the bowel terminated in the membranous portion of the urethra, by an aperture about the size of a lancet puncture, and not in the upper end of the bladder, as was originally imagined.

When the infant cannot be relieved by an incision in the perineum, the sigmoid flexure of the colon, or any other portion of the large intestine which may happen to be prominent, may be cut into through an opening in front, as was originally proposed by Littre. The descending colon, as was recommended by Callisen, perhaps even the sigmoid flexure, may be reached behind where not covered by the peritoneum, and thus that membrane may be avoided; but such proceedings have been attended with indifferent success, and considering the condition in which the patient is afterwards left, with an artificial
anus in the side, constantly permitting the escape of the contents of the bowels, fatal results are scarcely to be regretted. I have repeatedly now, on being consulted in such cases, stated the particulars fairly to the male parent, and have left him to choose: the decision has almost invariably been against any operation under such circumstances. Some years ago I opened the sigmoid flexure in an infant at the desire of the parents. Here I passed through the peritoneal cavity, and, after opening the bowel, stitched the aperture to that in the parietes. The result for weeks was most satisfactory, but I had to keep one of my dressers in frequent attendance, so that he might prevent the orifice closing. The parents now seemed tired of the attention the infant required, and though there was no impeachable negligence on their part, I had reason to think that there was little grief at its early death. In this instance no doubt life was prolonged by the operation.

In the adult the lower part of the intestine in some individuals becomes completely obstructed, by the contraction of a stricture, or in the progress of scirrhous and cancer of the rectum. Amussat, in such a case, strongly recommended the formation of an artificial anus higher up, and succeeded in relieving several patients in this way. Mr. Teale, of Leeds, Mr. Alfred Jukes, of Birmingham, and others have performed such operations. The latter gentleman has published some drawings of the parts, in an instance where he opened the descending colon behind the peritoneum in the lower part of the lumbar region: his patient died on the sixteenth day, and one upon whom Mr. Teale operated in March, 1842, died on the seventh day after.

This subject was extensively brought under the notice of the Royal Medical and Chirurgical Society by Mr. Cæsar Hawkius and others during the session 1851-52, and subsequently Messrs. Hilton, Solly, and Curling have also paid special attention to it. The reputed success of such an operation, although of a temporary character, might lead one unhesitatingly to resort to it in all cases which seem to demand this mode of treatment.

The proceeding is usually effected thus: A straight incision is made through the skin, three or four inches long, between the last rib and the crest of the ilium, a little in front of the quadratus lumborum, and the knife is carried successively through the external oblique, internal, and transversalis, when the back part of the descending colon, where it is uncovered by the peritoneum, may be reached and opened. It is a great advantage to avoid the peritoneum, but if it is accidentally or intentionally opened every care must be taken to prevent the contents of the bowel from escaping into the cavity. The best method of so doing will be to stitch the margin of the intestine and peritoneum together. Possibly the sigmoid flexure of the colon may be so much distended that it may appear best to make the opening there, in which case it will scarcely be possible to avoid opening the peritoneum. The actual wound of the peritoneum is perhaps of less consequence than the escape of the contents from the bowel into the cavity. The latter may be deemed a fatal complication.

Gastrotomy, or opening the peritoneum at any selected part for the
sake of discovering some supposed mechanical obstruction, is of even more questionable character than the above operation. When there is no positive indication by swelling or pain, it may be doubtful where the incision is to be. Where there is doubt I should prefer cutting in the linea alba, as that seems to be the central part;—the operator himself being able more readily to reach all parts of the interior from that situation. The wound in the linea alba may be three or four inches in length or more. The proceeding is indeed a forlorn chance, and the most slender hopes of success should be entertained. Once in a doubtful case I passed nearly the whole length of the jejunum and ilium through my fingers, when at last I found the obstruction in the latter caused by adhesions to the fundus of the uterus. I was able to divide these, and could then perceive the feculent matter urged onwards, so that the patient had an evacuation soon after. She sank speedily, however, from previous exhaustion.

The various forms of so-called piles are tolerably familiar to the surgeon, whether these be vascular turgescence of the mucous membrane, with or without solid edema, enlarged single veins constituting pouches, at the margin of the anus, in which, from time to time, blood coagulates and inflammation arises, or thickened portions of skin at the margin of the aperture. Small pendulous tumours are sometimes met with in the rectum, and most of such cases that I have seen have been mistaken in their character. Sometimes they have been considered hemorrhoids of the worst kind, and in other instances they have been considered cases of prolapssus of the bowel. If the surgeon is on his guard he will have no difficulty in recognising such cases. During defecation the protrusion is always distinct, it usually bleeds, but a little pressure causes it to pass within the anus. I have sometimes been led to suspect the nature of such a case by hearing that the neck of the protrusion seemed small, and, when I have examined with the finger, I have found, on moving its point carefully round the mucous membrane, a small peduncle attached to the tissue, about an inch or a little more within the anus. Such growths, rarely exceeding the size of a filbert, are easily drawn out of the anus, and, after a thread is put round their neck, they may be at once cut off with knife or scissors. The thread is a wise precaution against bleeding, which otherwise might take place.

A loose, flabby, expanded state of the rectum, and relaxed condition of the sphincter, are by no means unusual. Those thus afflicted have little control over the actions of the bowel. There may be either constipation or relaxation, in which latter state the patient has not the power to retain the contents of the bowel until a convenient period. Such cases are not particularly amenable to surgical treatment.

Often the rectum is obstructed either by the presence of cancerous tumours in the tunies, by valve-like projections of mucous membrane, or by contraction of the diameter of the gut. Cancer is common. It is best detected by the finger; its usual seat is about as far up as the point can reach. It may be as a hard mass projecting into the bowel, more at one side than the other, and covered with mucous membrane;
or more likely it will, by the time an examination is thought desirable, be already ulcerated, and have involved the whole circumference of the gut. In such cases only palliative treatment can be of avail. A projecting fold of mucous membrane may, with due precautions, be divided with a bistoury.

A stricture, which is usually a fibrous thickening of the tunics and contraction thereof at the same time, must be treated by bougies, or notched with the knife according to circumstances, which any one acquainted with the common principles of surgery may readily appreciate.

The skin around the anus is subject to a variety of ailments, some of which are perhaps peculiar to this region. The natural secretion from the skin in some individuals has a peculiarly irritating quality, and redness, thickening of the skin, and slight ulceration is a frequent condition resulting from this. Sometimes the thickening of the skin is the most conspicuous state, sometimes the ulceration, which herc usually appears as a radiated cracking of the skin about an inch round the anus. Usually in such instances there is great itching of the part, and there may be such a copious secretion of a thin sero-purulent matter as to wet and soil the patient's linen. In certain cases, if great cleanliness be not attended to, the thickening of the skin increases, giving rise to that condition technically called condyloma, or, in other instances, large warty-looking excrescences grow, which occasionally attain the size of the fist. In the latter state perfect cleanliness is impossible. The surface of the mass is composed of hundreds of little prominent studs, which have furrows between them where water cannot reach, and from whence a most offensive sero-purulent discharge constantly exudes.

In the first of the states above noticed, attention to the liver and bowels, with some simple astringent lotion or ointment, may effect a cure; but if there be considerable mischief the nitrate of silver may be necessary, or possibly the scissors may be of service in clipping away the diseased surfaces. With condylomata, or warty excrescences, I prefer this practice, under chloroform, to any other; and while I would, in an instance where nothing had been attempted, certainly try the effect of soap and water with the adjuncts above recommended, I should certainly not dwell long in hopes of effecting a cure in this way, but would speedily resort to the use of cutting instruments.

In some individuals, and in certain states of the constitution, a single crack in the mucous membrane or skin at the margin of the anus gives rise to an amount of suffering seemingly far out of proportion to the extent of the local lesion. I doubt if this has yet been properly and well accounted for. The periodical stretching of the part during defecation seems to have a most injurious influence, for during the time and immediately thereafter there is excessive pain, which may continue for minutes or hours. Whether the distress arises from the stretching of the crack (fissure in the anus is the common term), or from contact of irritating material, may admit of question, but it is certain that in such instances, when the bowels have been attended to,
and local soothing applications, also stimulants, including even the nitrate of silver, have been resorted to with no good effect, there is no remedy equal to a division of the fissure and part of the sphincter muscle, or even the whole of it, with the knife. In some of these cases a distinct ulcer may be felt within the anus immediately above the sphincter; and in such the free and early use of the knife is of admirable benefit. The introduction of an ordinary probe-pointed bistoury on the point of the forefinger, so as to cut outwards and divide for half an inch or a little more in the line of the disease, is all that is required in this way; a bit of oiled lint may be placed in the gap, and thereafter union by granulation must be attended to.

In some instances, without there being any positive disease in the skin or elsewhere, there is that state which is familiarly spoken of as prolapsus ani. This term has been applied to various conditions. A true prolapsus of the anus in reality, perhaps, never exists. But prolapsus of the rectum through the anus does occasionally occur, and the condition to which the term is probably most frequently applied, is prolapsus of the swollen mucous membrane. The latter affection I believe to be very common—it is, in fact, the ordinary state of internal piles; the other is more rare, although it is every now and then met with. It is occasionally the result of long continued irritation of the bladder, as from stone, but it is not unfrequently met with irrespective of such complaints, and in instances, too, where it is impossible to make out any special cause. Where there is such a cause as stone in the bladder, or derangement of the bowels in children, the local mischief will disappear as the cause does; and in other instances some active surgical interference is necessary. In all such cases there is a great laxity of the skin on the verge of the anus, and if radiated slips of this be taken away, an amount of benefit results which is really astonishing. Such an operation as is here alluded to I have performed very frequently with the most satisfactory results. It appears as if in such cases the skin had become so redundant as to prevent the sphincter from closing perfectly, for no sooner are the slips of skin, two, four, or six, as may seem needful, removed, than the sphincter seems to close with a precision which was absent previously. In some instances, after taking away considerable patches of skin, there still seems a redundancy, and the scissors may be applied again with great advantage. I occasionally combine this practice with the use of ligatures to the internal piles, whilst in certain instances it seems all that is required, even in cases where the prolapsus of the rectum is of four or six inches in extent.

Operations are frequently required in cases of hemorrhoids. During the inflamed condition of these tumours, such treatment is seldom advisable. The ordinary means of subduing that disease—such as leeches, fomentations—especially those which are termed anodyne, rest, the horizontal position, and laxatives, form the only reasonable method of practice in such instances, although sometimes when one or more of the inflamed projections are very hard and prominent, and formed seemingly each of a single varix with a clot of
blood within, a lancet may be advantageously thrust in, or if the base
be not extensive, the scissors may be used to snip away the greater
part of the disease. But in general such interference cannot, in my
opinion, be deemed good practice. I believe, however, that in the
chronic condition of such tumours much more may be done by active
surgical interference than is commonly supposed. Here I allude
principally to that relaxed and vascular condition of the mucous mem-
brane of the gut which is far from being unusual in the adult, and
which is the cause of so much distress whilst at stool, both from the
copious discharges of blood and matter, as also from the eversion or
prolapsus which occurs at the time. I may also include those
examples where one or more hard tumours are connected with the
lower part of the rectum, immediately within the anus, which pro-
trude on these occasions, or sometimes escape through the sphincter
whilst the person walks, and for a time become, in a manner,
strangulated.

In either of these instances, supposing that the ordinary treatment
by means of astringent lotions and applications in the form of decoc-
tions and ointments, and a due regard to the state of the bowels,
exercisc, and so forth, produces no benefit, the use of caustics may
effect a cure. Common lunar caustic may suffice, but in these affec-
tions nitric acid was particularly recommended by Mr. Cusack,
and Dr. Houston, of Dublin, the latter of whom published a paper on
the subject in the twenty-third volume of the Dublin Journal of
Medical Science, wherein he adduced many examples of its utility.
The affected part, when protruded by an effort of the patient, is
touched with a bit of wood which has been dipt into strong nitric acid,
then smeared with oil, and returned within the sphincter. Little pain
is felt, and a thin slough separates in a few days: as the sore heals
the rectum gets into a better condition than previously, and, in all
probability, there will be a complete cure. I have frequently resorted
to this practice, and can speak in unqualified praise of its efficacy. I
have often used the acid in examples where patients dreaded the
application of threads or cutting instruments, when I had little hope
of a favourable issue, and have been pleased in proportion to find that
a single touch has sufficed for a cure. Instead of desiring the patient
to strain and so cause the diseased parts to protrude, I have latterly
made use of a glass tube, like those made of metal as delineated by
Scultetus—a kind of speculum—with a hole at one side, through
which, when the instrument is passed into the gut, I can examine the
condition of the affected surface, and at the same time apply the acid
freely without coming in contact with the other parts of the mucous
membrane. The glass is so thick that there is no risk of the tube
breaking, and the material, unlike all others used in the construction
of specula, is unaffected by the acid. The tube, shaped as seen in
figs. 413 and 414, is between three and four inches long, and its upper
extremity is smooth, round, and closed, so that the contents of the
gut cannot pass downwards at the time it is in use. The opening in
the side may be larger than that represented in figure 413, and it may
have various shapes. Latterly I have chiefly preferred the situation of the aperture and a shape such as displayed in figure 414. The

*Fig. 413.*  
*Fig. 414.*

instrument in question is of glass alone, or it may be silvered on the outside, and made in all respects similar to the speculum for the vagina which I devised many years ago, and which is now in very general use when such a mode of examination is needed.

In the event of the above plan not succeeding, I should strongly advise the removal of the offending parts by means of ligatures, as being preferable to the knife or scissors. Such a proceeding as the following may be resorted to: The patient—having had the gut cleared by an enema of warm water, should be desired to lean forward upon a bed or lie on his side, present his breech in a good light to the surgeon, and strain so as to cause the lower part of the mucous lining to protrude: then the surgeon should, with a curved needle of the common sort (p. 34), or that set in a handle (p. 35), introduce a double ligature of stout thread or thin whipcord through the base of the part intended to be removed; when, by drawing a firm noose on each section, the part will be completely strangulated; and, provided the threads have been drawn sufficiently tight, will drop off in the course of six or eight days: after which the sores speedily heal, and the annoying disease will be permanently cured.

The mode of applying ligatures, as described at page 155, for the treatment of aneurism by anastomosis may be resorted to in such cases. In general, however, I am content with the method just described.

If the relaxed and vascular mucous membrane, or the tumour, be removed with cutting instruments, the hemorrhage may be very
troublesome; and, in addition, large open wounds will be left, which will heal slowly, and possibly the interior of the gut may after all remain of a more capacious size than may be desirable. By the proceeding above recommended it will be observed that, besides avoiding all bleeding,—not more than a few drops of blood will be lost,—the interior is contracted in diameter at once; for, supposing the punctures to be about an inch separate, when the threads are drawn tight the part included in the different loops will be compressed into a size so small, that when the slough separates the open sore will not be larger than may be covered with the tip of a finger. Judging from my own experience of this practice, I have no hesitation in stating, that it seems to me so superior to the other modes alluded to, that it should always be preferred. In such a proceeding, as in many other operations in this region, besides some amount of pain and constitutional irritation, the patient may for several days after have difficulty in voiding urine; indeed there may be complete retention. The catheter, however, will seldom be required, as a little camphor and hyoscyamus, or such like remedies, with the hip-bath, will seldom fail to put all to rights.

There is great diversity of opinion as to the propriety of applying ligatures, or using the knife in instances such as are above alluded to, and I believe, too, that there is considerable difference as to where the ligatures should be applied. For my own part I should never think of applying a ligature which should implicate the skin. The scissors I fancy do the work more efficiently as well as more rapidly; and with chloroform the patient cannot feel pain, while, probably, afterwards the pain from the cuts will be less than from the presence of ligatures. I have an equally strong opinion as to the impropriety of cutting internal piles with the knife or scissors. There may be such an internal bleeding as to endanger life, as I have seen; yet while I admit that such a practice may be followed again and again without mischief, I would earnestly caution the young surgeon against rashness in this respect. In one instance—having become emboldened from using the scissors with impunity in a variety of cases—I nearly lost a patient from hemorrhage into the rectum from a small portion of a wound in the mucous membrane which passed within the sphincter. On clearing the rectum from a large collection of blood and applying ice the bleeding stopped, but probably this was as much the result of the faintness from loss of blood, as from any such surgical means that were adopted. Since recording this case, I have had another not unlike it in most respects. Eight hours after the operation the patient looked well nigh dead, but fortunately the bleeding ceased, and by the administration of stimulants he rallied, and ultimately did well.

The presence of ligatures produces, in most instances, considerable pain, particularly if any skin be included, and, as some imagine, may be the cause of various evils, especially tetanus. I have twice seen this fatal disease under such circumstances, but am doubtful if the ligatures have actually contributed to this end. To avoid any such risk and to secure from hemorrhage, Mr. Henry Smith uses the scissors
to remove the excrescences, and thereafter the actual cautery, to sear the vessels. His operation is ingenious and effectual. The part to be removed, especially if it be an internal hemorrhoid, is drawn down with forceps or hooks, and then embraced with the blades of a clamp, which are firmly squeezed upon it. The scissors are next applied, and thereafter the cautery. The clamp has on each blade a plate of ivory, which prevents the heat distressing the patient. I have often seen Mr. Smith apply this practice in King's College Hospital, and have been much pleased with the results, both as regards pain and rapid convalescence. Through the kindness of this gentleman I am permitted to give a representation (fig. 415) of this instrument, as last described by him in The Lancet for 7th August, 1869.

Fig. 415.

Suppuration in the vicinity of the anus may be treated according to those general principles contained in the Chapter on Abscess in the first part of this volume. This is one of those instances where the practitioner should make an opening at an earlier period than he might possibly deem necessary in many other parts: for if an external incision be not soon made, the matter may perhaps burst into the rectum, and thus the case may become more complicated. Under almost any circumstances, the sac of the abscess is likely to pass into that condition termed sinus, when the treatment may be such as is recommended in the chapter on this subject. It will rarely happen that the sinus (here technically termed fistula in ano) does not require to be laid open. Occasionally such cavities close spontaneously, but it much more frequently happens that the aperture remains patent, and continues to discharge a thin matter, which keeps the patient's linen constantly in a filthy condition, unless he wears some covering upon the part. Sometimes the end of the sinus closes for a time, and a cure is supposed to have taken place; but ere long an uneasy sensation, perhaps throbbing, is felt in the vicinity, when at last the cicatrix bursts, and the discharge becomes as copious as before. The opening may be single, double, or more; it may be on the skin or mucous membrane; or possibly the sinus may open both on the skin and gut. Sometimes two openings will run into one sinus; and in other instances several fistulae, which do not communicate with each other, may exist around the anus. The external end of the sinus may be close to this aperture,—an inch off, or even two or three—it may be towards the scrotum or...
in the direction of the sacrum, but is most frequently at one side, and usually about midway between the anus and tuber ischii. The opening in the mucous surface may be close on the verge, or it may be high within the rectum. Some authors have asserted that the inner opening is never beyond an inch from the anus—it rarely is; but I have myself often laid open sinuses as high up as the blade of a bistoury would reach, and have treated cases at all intermediate distances. In one instance the length and thickness of parts between the fistula and the gut will be considerable, whilst in another the partition will be short and thin,—perhaps not more than the thickness of the gut itself—nay, even the mucous lining; for occasionally matter will so burrow between the muscular fibres and the latter membrane as to establish a fistula, and one which is more apt to be overlooked than those of a conspicuous kind.

The treatment of fistula in ano admits of a variety of modifications. Those who are the subjects of the disease usually look upon it with much dread, and will submit to almost any measure which shall offer a chance of cure without a cutting operation. A persistence in the use of lotions, especially astringent injections thrown into the sinus, and well-regulated pressure, will occasionally suffice, but if these will not bring about a fortunate result, some other method must be resorted to. Mr. Luke revived the old method of passing the end of a stout thread through the sinus, into the rectum, then bringing it down through the anus, and so by including the parts between in a firm noose, which can be gradually tightened, they are cut through, and the sinus being thus laid open, heals by granulation. The method is said to induce little pain, and the patient may be permitted to move about during the period. Possibly some, who would eschew any proceeding with the knife, may be induced to submit to the application of a thread, yet the practice having been so long abandoned by the profession, and doubtless for good reasons, will not, I imagine, be easily revived again; nor, indeed, does there seem much occasion for it, as the treatment with the knife, if judiciously resorted to, seems to offer all that can be reasonably expected under the circumstances.

The usual operation for fistula may be performed thus:—The patient should lean over the margin of the bed, table, or back of a stout chair, or lie as described at p. 655, and the surgeon should stand, or sit himself sufficiently low, to get a clear view of the perineum: he should then introduce the end of a probe-pointed bistoury (p. 88) through the external opening, and push it slowly along the sinus until it reaches the upper extremity; then the point of the forefinger of the left hand, smeared with oil, should be passed into the anus, and if the instrument has not yet penetrated the gut, the operator should cause it to do so, either through the opening in this situation,—supposing that one is present,—or should thrust it through partly by pushing with his right hand, and partly by scratching with the nail over the point of the blade; and as soon as this is accomplished, the bistoury and finger must be drawn downwards, much in the attitude represented in figure 416, so that all the textures between the sinus and the interior of the rectum shall be divided, and the two be as it
were thrown into one chasm. In some instances it may be found most convenient to hook the apex of the finger behind the point of the blade, and in a manner force the cutting edge through the parts to be divided. It is scarcely requisite to point out, that if the opening in the skin has been some way from the anus, the sphincter muscle must be divided in the incision; indeed some surgeons seem to imagine that the success of the operation depends chiefly on this circumstance, although for my own part I imagine that there are many instances in which that extent of wound is not required, either physically or physiologically. When the sinus is thus laid open, it is well to push the finger into the track to ascertain that there has been no offset from it. Frequently a space may be discovered under the skin, and the knife should be so used as to expose it fully. This tissue may be freely laid open, but when the sinus extends high up there may be danger from hemorrhage. I believe it is best to open a sinus throughout, although in certain cases it has been found that the upper portion closes during the treatment of the wound in the lower end. A slip of lint moistened with oil should then be passed to the bottom of the wound, and the patient should be kept in bed until the cavity heals by granulation. Doubtless in such cases the success depends greatly on the manner in which the operation is performed, and much also may be attributed to care in dressing; for unless the lint (usually covered with a little olive oil or spermaceti ointment) be kept in the bottom of the granulating surface, the external part of the wound may close, and a sinus still remain. This, however, but rarely happens; whilst, on the other hand, with every attention after a well-executed operation, ulceration or abscess may come on, new sinuses may form, and the proceedings may all require to be repeated. In such a case, as indeed in all instances of fistula in ano, it may be well to ascertain the condition of the patient's lungs; for the coincidence of fistula with disease of these organs is often remarkable. I need scarcely state that a surgeon would seldom be justified in interfering with a sinus under such circumstances. But fistula in ano will sometimes show itself when there is no suspicion of disease in the chest. Some time ago I had occasion to lay open a sinus on the verge of the anus in a man about fifty years of age, whose appearance did not in any way betoken even a disposition to chest affections: at first the wound went on favourably enough, but in three
weeks, when it should have been nearly healed, its condition was much the same as within a few days of the operation, only that there seemed less action on the surface: it continued thus for nearly two months, notwithstanding every variety of treatment which could be feasibly resorted to, both as regarded local and constitutional means, when more decided change of air was recommended. During all this time there was no complaint of any pain within the chest,—no circumstane to lead to suspicion even that something was wrong,—yet in the course of three months this person died of rapid consumption, the wound keeping open all along.

If two or more sinuses are present, they should be exposed in the same way, at the same time, and treated in a similar manner. On one individual I have laid open five deep sinuses at the same period, and after he had been repeatedly operated on before. By great care all these wounds healed kindly, and the patient was ultimately enabled to resume his duties as assistant-surgeon in the Navy. Here there was complete loss of power over the sphincter for a considerable time; but this unfortunate condition gradually wore off.

Unless the wound be very deep, there is seldom any bleeding likely to do harm. If it be more copious than may be deemed safe, the gap should be firmly stuffed with lint, and a pad may be retained over it by a bandage; the cross of the T should be tied round the waist, and the tail brought along the perineum, to be fastened in front with such tightness as to keep on any pad which may be placed on the anus or neighbouring parts.

If the sinus is on the left side of the perineum, the surgeon may find it most convenient, when the patient stands as above directed, to use the bistoury in the left hand; or if he has not sufficient ambidexterity for this, he may have the patient placed on his back, with his knees in the air, as for lithotomy. In any position a couple of stout assistants will be of service to keep the patient steady; for if he is at all unruly, as often happens, the proceedings will be rendered somewhat annoying, and possibly the blade of the bistoury may be broken in the wound during the struggles. I have seen this happen in the hands of a most dexterous operator; and at all times, whatever force may be used with this instrument, care should be taken that the blade does not wheel round, so as to be strained sidewise, for it is then very apt to snap. The cutlers often erroneously make a kind of notch near the heel of this instrument, which causes it to be very defective in this situation; and it is here where it usually breaks. The flat surface of the blade should slope gradually from the handle to the point. With chloroform, which is almost invariably used, the patient lies on his right or left side at the will of the surgeon, who stands or sits near his work in accordance with his own convenience. The straps recommended afterwards for lithotomy are very useful in this operation, applied on one or both sides.
The division of other sinuses in the perineum, such as those constituting urinary fistulae, requires no special notice here, neither does it seem necessary to refer particularly to the manner of introducing instruments into the rectum, although cases demanding such manipulations are of frequent occurrence in the practice of surgery. Here, as in other parts of the body, the young surgeon should accustomed his finger to the examination of the interior of the gut, whether for the sake of ascertaining the condition of the tube itself or the contiguous parts, such as the bones, prostate gland, and neck of the bladder, or for detecting the presence of foreign substances. In the latter instance, it is occasionally requisite to introduce instruments, perhaps lithotomy or midwifery forceps, to extract large substances, such as pieces of wood and stones, which have been introduced by the persons themselves. In the Medical Gazette for 19th August, 1842, Mr. Russel, of Aberdeen, gave the history of an individual who seemingly had a remarkable propensity for introducing stones within the anus: he (the patient) himself had extracted, after the surgeons had failed, one weighing thirty-two ounces, and another had been removed with midwifery forceps by Dr. Moir, six months previously, weighing twenty-nine ounces. In the same journal, February, 1842, there is a case related where Mr. B. Phillips extracted, after the patient's death, a portion of a walking-stick; and several examples of a similar nature are referred to. In some instances the fingers will suffice to extract a small object, such as a bone which may have been swallowed and arrested in its course downwards in this part of the canal; and on other occasions the fingers may be most advantageously used in severing and extracting portions of hardened feculent matter on which ordinary enemata produce no effect. Sometime ago I had an interesting case of this kind to attend. An old gentleman had been in the habit of using bougies for the rectum, chiefly to please his own fancy, and one day, having passed one up its full length, he let it slip and got beyond his reach. Several surgeons failed to relieve him of the bougie. The gentleman who came for me informed me of the facts, and I went prepared accordingly. With extreme difficulty I could touch the end of the bougie with the tip of my finger. I fortunately succeeded in seizing the instrument with lithotomy forceps, and readily extracted it. The bougie was nearly one inch in diameter, and about nine long, and, curiously, seemed to cause little inconvenience in the gut where it had been lodged.

Every now and then we meet with cases of large accumulation of feces in the rectum. Such a state is apt to be overlooked. It occurs, I believe, more frequently in the female than in the male, but I have seen it in both. There is great desire to empty the bowel, but all efforts are unavailing. The female may compare her condition to the pangs of labour. With such symptoms, if the bowel be examined, it may be found filled with a mass the size of a fist. By running the finger, or any convenient instrument across, it may be broken up and partly hooked away; and ultimately, to the great relief of the patient, wholly got rid of by the aid of injections of tepid water.
The removal of the anus and a portion of the rectum for malignant disease, such as scirrhous and open cancer, as recommended and followed by Lisfranc, seems to have few advocates in this country. My old colleague, Mr. Lizard, used occasionally to perform this operation, and I have seen one of his cases where, in a man of middle age, he had, some years before, removed several inches of the tube. The parts appeared as if no such proceeding had been resorted to, and the patient had complete power over the lower end of the remaining portion of the bowel. Mr. Lizard was in the habit of removing the verge of the anus in that condition wherein I have recommended the use of ligatures, and operated thus: — the breech being properly presented, he seized the swollen and protruded parts with a vulsellum (p. 474), with which he pulled them still further down; next with a bistoury he effected their separation, by incisions made in the line of the circumference of the gut; then he stuffed a large hard compress, previously prepared for the purpose, into the wound, which he retained firmly by means of a bandage, and thereby suppressed all bleeding. A similar process was followed, when larger portions of the gut were removed, the operations being in most respects like those done by Lisfranc. I have in my own experience met with only one instance where I deemed such a proceeding advisable, and the result under the circumstances was very satisfactory.

CHAPTER V.

DISEASES OF, AND OPERATIONS ON, THE SCROTUM, TESTICLE, PREPUCE, AND PENIS.

Diseases of the scrotum and its contents are numerous, interesting, and important. When inflammation is present, there is a remarkable disposition to edema, and frequent reference has just been made to this subject at p. 75 in the Chapter on Effusion. Most of the phenomena of inflammation are well marked on this part of the skin, and some kinds of disease are in a manner peculiar to this locality. In particular a certain form of cutaneous tumour, which ultimately changes into a malignant ulcer, is more distinctly marked here than anywhere else. This form of disease is familiarly known under the name of "Chimney-sweeper’s Cancer," having been so named by Pott and others because it appeared to be peculiar to those engaged in this occupation. On that point I have always been sceptical, although I admit that most of the instances I have met with have been on those
who have been thus engaged. I have seen it, however, on persons who have never had more to do with soot than ordinary individuals. A similar disease may be seen on the skin in various parts, particularly about the face and hands, and in one example of the latter sort, the patient attributed the mischief to handling or working with guano; this, however, I attributed to a coincidence. The disease, when on the scrotum, usually shows first as a small wart, which causes little or no trouble; by-and-by, however, it enlarges, and, if let alone, runs into ulceration. This action extends with varied degrees of rapidity in different cases, and, unless checked, gradually involves the greater part of the scrotum, and ultimately attacks both tunica vaginalis and testis. By this time the glands in the groins are affected: perhaps ulceration extends or begins there, and if the patient is not carried off by sudden hemorrhage from some large artery in the groin, he gradually sinks from exhaustion. Unless these tumours or ulcers are removed at an early date by caustic or the knife—and the latter has been chiefly used here—there is no chance for the patient. Even when an operation has been performed the disease is apt to return, and in this respect it follows the characteristic features of true cancer.

Blows on the scrotum are often followed by remarkable effusion of blood into the cellular tissue. Curious changes of colour, from dark blue to light yellow, appear in course of time in such cases, and generally the appearance from swelling, slight inflammation, and colour, is less alarming than the uninitiated are apt to suppose. If the blood is regularly diffused through the cellular tissue little harm results. It is usually all absorbed. But if a quantity collects in one part it may induce suppuration, or at all events may possibly require to be let out with the knife. One of the largest collections of blood I ever saw in the cellular tissue of the scrotum followed the use of a trocar in tapping for hydrocele. In that instance an artery of some size had been punctured, and the scrotum was in a few hours as large as a child’s head. Happily no ultimate mischief occurred in this case. The patient was much shaken, partly by loss of blood, though chiefly by fright, but in time absorption took place, and the old hydrocele resumed its usual appearance and course. It has since been tapped repeatedly without any similar evil.

Accumulations of serum in the tunica vaginalis testis, or the spermatic cord, constituting the usual forms of the disease termed hydrocele, are of common occurrence—especially that in the tunica vaginalis, and its treatment demands a large proportion of the ordinary surgeon’s duties in this situation.

The diagnosis of such cases is often interesting and difficult. When the effusion is in the tunica vaginalis its character is generally easily recognised. It may follow a blow and subsequent orchitis, but it more frequently comes spontaneously. Fluctuation, and, above all, transparency, are the most palpable symptoms; but when the scrotum is thick these are not always distinct. An exploring needle or a fine trocar and canula will settle the question, and certain negatives—
such as the absence of swelling in the course of an inguinal hernia, particularly in the early stages, and the absence of symptoms of disease of the testis, will set aside any hesitation about resorting to a puncture. The swelling being originally at the bottom of the scrotum is also a characteristic. In the early stage of hydrocele of the cord the small round or oval swelling in that part is strongly indicative. The disease rarely, if ever, begins in that part of the cord which lies within the inguinal canal; it is commonly close upon the testis, and here, as with the other form of hydrocele, if in the course of enlargement the canal seems implicated, it will be found that the progress has been from below upwards. The testis is generally more distinct than in the other form, lying below and in front. The disease can hardly be taken for any other, particularly as most others have peculiarities of their own. As to whether the hydrocele be of the cord or of the tunica vaginalis, is of little practical moment. In their earlier stages they can easily be distinguished, but when large there may be difficulty in recognising the one from the other. In the event of tapping, an examination of the fluid underneath the microscope will indicate the absence or presence of spermatorrhea. In the latter case the hydrocele will certainly be in the cord. The presence of these animalculi in the fluid from this quarter was first pointed out by Mr. Liston, more, perhaps, as a physiological fact than as having any practical bearings. The fluid from this hydrocele is usually paler than that from the tunica vaginalis, but if there be any special anxiety or curiosity on the subject, it may be settled by a simpler and equally certain test. If a few drops of nitric acid be put in the fluid, if it be from the hydrocele of the cord only, a light white cloud will appear; but if from the tunica vaginalis, a white almost solid mass of albumen will sink to the bottom. Albumen seems in greater quantity in this fluid than in any other serous secretion, and the test may be thoroughly relied on. By boiling, the whole will coagulate almost like the white of egg. This is a clinical fact, which I learnt by myself many years ago, and I have often demonstrated it in the Theatre of King’s College Hospital. It, like the other, is more interesting physiologically than from any practical bearing.

Here a variety of methods of treatment may, in accordance with circumstances, be resorted to: First, after it has been ascertained that the customary means of promoting absorption, such as are alluded to in the Chapters on Inflammation and its consequences, in the early part of this volume, have been found to be of no avail, as will usually be the case, the fluid must be withdrawn (say) from the tunica vaginalis—a proceeding which may be accomplished in a variety of ways, the most common being by means of a trocar and cannula. The manoeuvre may be effected thus:—The scrotum should be seized in the left hand, gently raised, and squeezed so as to render the skin tense in front; then the point of the trocar held in the right hand, with the apex of the forefinger almost close upon it, should be thrust into the front of the swelling, about midway between its upper and
lower end, at an interval between the vessels of the scrotum. As soon
as the instrument has entered, which will be readily known by the
cessation of resistance, the finger must be raised, and as the trocar is
withdrawn, the canula should be thrust somewhat deeper, where it

must be allowed to remain until the fluid has run off. Sketch 417 will give an idea of the above description.

In many instances, especially on a first tapping, such a small instrument as that referred to at p. 468
will suffice for this operation; but possibly it may be considered too slender for ordinary purposes, and
one about a line in diameter, or a little more, is usually selected. The trocar and canula when con-
joined are difficult to keep in order. The canula cannot after use be easily dried at the moment, and
unless it is so the steel is very likely to be rusted. Figure 418 represents a very convenient improvement with regard to
the instrument. The trocar and canula are here displayed in a wooden
or ivory case:—The trocar b, in one compartment, the canula c,
in another, as shown by the dotted lines. The screws at a and a permit
the sheaths to be undone, when the canula can be placed on the trocar
for use. When the operation is finished, the component parts of the
instrument may be again adjusted, as shown in the sketch, and thus the
point of the trocar can be guarded against mischief, whilst the canula
can be allowed to dry in its own place.
If the part above referred to be selected, and if the puncture be made nearly at right angles with the surface, there will be little risk of injury to the testicle, as this gland is almost invariably at the back of the swelling. It is injured sometimes when the trocar is thrust too deep, especially when the hydrocele is small; and on all occasions it is well to ascertain the position of the organ beforehand, as in some instances it lies so much in front as to be in considerable danger. If the want of transparency does not indicate its situation, pressure with the fingers will usually do so.

If a common sewing-needle, a pin, or a cataract-needle, in accordance with the original suggestion of Dr. Cumin, of Glasgow, be introduced once, twice, or thrice,—once will often suffice, a similar effect will be produced, though in a different way: the fluid escapes through the aperture in the tunica vaginalis, gets diffused into the cellular tissues of the scrotum, and is rapidly absorbed, so that in eight-and-forty hours the swelling will entirely disappear. This may not happen in all instances, yet it will in a number, provided the scrotum is otherwise in a healthy condition, and the fluid does not exceed four or six ounces in quantity. Some years ago, when this mode of treatment was brought under the notice of the profession by Mr. Lewis, it attracted a good deal of attention; but so far as I can perceive, it has undeservedly passed out of notice again,—perhaps in consequence of the oversanguine statements of those who advocated the plan, that it would effect the cure of the disease; but this it is no more likely to do than tapping is to cure ascites. It is well known that, after the use of the trocar, either in the abdomen or scrotum, the respective diseases are occasionally cured; and the same will sometimes follow the use of the needle as above recommended; but it is equally certain that such happy results rarely ensue.

If the hydrocele forms again, one or other of these processes may be repeated as often as may be desired; but it is customary after the second or third time to resort to some method of altering the action of the serous surface,—a proceeding which is usually brought about by inducing inflammation. This may be done in a variety of methods; but among surgeons of the present day that by injection has been most frequently resorted to. The proceeding is accomplished thus:—

The serum being drawn off in the manner already directed, a small syringe, provided with a moveable stop-cock nozzle, is applied to the end of the canula, and the tunica vaginalis is again distended nearly to its full extent by a fluid of a different quality from that which has previously been present. A mixture of port wine and water (two-thirds of the former to one of the latter) has been generally used since this practice was revived and so strongly recommended by Sir James Earle; but the wine will do by itself, and also the water, although the former would perhaps be too stimulating for the generality of cases, and the latter too little so. Solutions of salts, as alum, acetate of lead, sulphate of zinc or of copper, corrosive sublimate, and other kinds, of lime-water, acids, of alcohol, and of various tinctures, infusion of roses, or of oakh-
bark, have all been used for the same purpose; in short, any change of fluid seems, in most examples, to be sufficient to produce the desired effect. Whichever is selected, it is allowed to remain in the cavity for the space of four, six, or ten minutes, or until the patient feels some pain in the testicle, extending perhaps, up the cord and into the loins, when it is allowed to pass away by withdrawing the stop-cock nozzle; then the canula itself is removed, and so the operation is completed. The patient should keep his couch for a few days, as in all probability considerable inflammation will ensue. The action on the serous surfaces will afterwards be so far changed, that the fluid will not again collect. It can scarcely be doubted that in the generality of instances adhesion takes place between the tunica vaginalis and that portion of it named reflexa, although doubtless in some the cavity remains much as before—though the action on its surface is changed for the better, either by diminished secreting, or increased absorbing powers. Sometimes, however, a sufficiently severe inflammation, or at all events the necessary change of action, cannot be produced in this way, even after repeated trials, and as the patient may be anxious to have the disease cured, it can be accomplished in other ways: a seton may be passed through the cavity—a plan much extolled by Rae and Pott; it may be cut into,—the favourite and successful practice of Benjamin Bell; or a portion of it may be removed entirely; and in any of these methods it is evident that a more severe inflammation is certain to be excited. The seton, as I have seen, may produce alarming inflammatory swelling. With incision, or if it be combined with excision, the wound must be stuffed with lint, so as to induce granulation on the serous surfaces, which ultimately unite by adhesion and obliteration of the cavity. The latter process, I imagine, is also usually the result of the seton.

Occasionally I have found the following method answer very well. After using the acupuncture needle, and finding that the whole of the fluid had not been absorbed, or that a new collection was forming, I have with an ordinary sewing-needle passed a piece of common linen thread into the cavity, in the form of a small seton, such as has already been referred to in the Chapter on Aneurism by Anastomosis. This has traversed the scrotum and cavity for about an inch, and has been allowed to remain for one, two, or three days, according to the apparent extent of inflammation. As soon as the patient has complained of pain, and the parts have begun to swell, the thread has been withdrawn, and a radical cure has generally been the result. The puncture and the presence of the thread have usually permitted the fluid to escape into the cellular tissue, and, as the thread has come into contact with the testicle, the desired and requisite amount of inflammation has been more certainly produced.

One or other of the above plans must insure the obliteration of the cavity; and it is easy to perceive that some of them may be modified in various ways; as, for instance, with the needle the surfaces may be scratched in such a manner as to induce inflammation, while at the same time vent is given to the fluid. A fine trocar and canula may
also be used, the point of either being caused to graze the testicle. But the plan now most in favour, is that which has been brought under the notice of the profession in this country, by my friend, Sir Ranald Martin, formerly surgeon to the Native Hospital in Calcutta. Instead of throwing in several ounces of port wine or other fluid, this gentleman, by means of an ordinary urethra syringe, passes through a narrow canula, which has already been used in tapping, a small quantity of solution of, simple tincture of iodine (one drachm of tincture to three of water), which he allows to remain in the cavity— withdrawing the canula as soon as it has been introduced. The requisite amount of inflammation is thereby produced; and, as Sir Ranald has pointedly stated in his excellent paper on the subject, in the second volume of the Lancet, for 1841-2, without any risk having been incurred of the port wine being infiltrated in the cellular tissue of the scrotum—an event which, in the ordinary operation was probably not so rare as some suppose. I have myself known four instances of this unhappy mistake. Most of our leading surgeons have now resorted to this practice with the iodine; but the amount of experience acquired by the professor among the natives of the East, who seem peculiarly liable to this disease, puts all that can be stated by a European practitioner into small compass; for whilst a surgeon, possessing even tolerable opportunities here, can speak only of his dozens of cases, or hundreds at most, Sir Ranald Martin can adduce thousands! and these, too, treated within the short period of eight years. I have learnt from others who have practised in India, that the method has answered equally well in their trials of it, and I believe it has proved beneficial in equal proportion in other parts of the world.

Within the last thirty years I have almost invariably adopted this practice when a radical cure was advisable, and have rarely seen it fail. Only once has the inflammation proved distressingly severe—a case where the health was otherwise indifferent. Usually the after- consequences are so trifling that patients move about as if nothing had been done. Some years ago I operated on a case of double hydrocele, and injected only one side at first. In a few days, the patient, having suffered no pain in the interval, insisted that the other should also be treated in the same way, and although the immediate effect was much the same as after the first proceeding, the cure was perfect on both sides. Usually within the first forty-eight hours the effusion into the serous cavity is nearly as great as ever, and there is also some slight oedema of the scrotum; the testicle, too, becomes enlarged, but in a few days all these swellings subside, and at last the parts are left in a natural condition—unless, indeed, it be that there is adhesion between the surfaces of the tunica vaginalis—an effect which I doubt not occurs in most examples of the kind. The apparatus which I make use of is more portable than the old metallic syringes, and I have found a glass one least liable to objection, as it resists the action of the iodine better than any other material. Figure 419 represents the size and shape of the instrument which I use: the nozzle is tipped
HEMATOCELE.

with silver, or, as some prefer, with platinum, and it is made to fit accurately the end of a canula of corresponding size. If desired, the length of the glass tube may be graduated; but as it is not necessary to be particular to a few drops, it is sufficient to know how much the syringe contains, which may be from a drachm to a drachm and a half,—a quantity sufficient, in my opinion, for the largest tumours of the kind.

Sir Ranald Martin has informed me that he always used the simple tincture of iodine, and I have had reason to fancy that its effects are more certain than those of the compound. A precipitate of iodine occurs where the simple tincture is diluted with water, but this constitutes no objection to its use. The above plans, modified by circumstances, will be also applicable to hydrocele in the spermatic cord.

Sometimes, in tapping for hydrocele, a vessel of considerable size, probably actually in the tunica vaginalis, pours blood into the cavity, which is thus soon filled by blood after the serum has run through the canula. On other occasions, and how or why we cannot tell, a collection of blood in the cavity is the result of a general oozing. I have noticed this particularly in cyst or hydrocele of the thyroid body. There may be both blood and serum in certain instances, even before tapping has been resorted to. The diagnosis of hematocele is usually more difficult than that of hydrocele. The absence of transparency is puzzling, and it often happens that even experienced surgeons mistake this condition for disease of the testis. The testicle is usually healthy in such cases, although it often happens that the tunica vaginalis, both covering it and where it lines the scrotum, is greatly thickened. It has often happened that the testis has been needlessly removed in such cases. The chief characteristic of this disease which I have been able to make out in the course of my experience, besides opacity and the absence of symptoms of disease of the testis, is that the swelling undergoes sudden varieties in bulk,—at one time appearing much larger or smaller than at another, as occasionally occurs in hydrocele. I do not consider this an absolute criterion, but if this feature be remarked, it may serve to put the surgeon on his guard, and so save him from the awkward mistake of removing a healthy testicle.

It rarely happens that hematocele disappears spontaneously. It is well in such cases to allow plenty of time for observation. Sometimes a kind of erysipelas-like inflammation ensues, particularly in cases of rapid development, and whether in this or a quiescent state the surgeon usually makes an incision about two inches in length, and lets out or scoops away the fluid and clots of blood and fibrin. After this a bit of oil or wetted lint is placed within the cavity, which gradually closes by granulation, and thus both hydrocele (if there has been one) and

Fig. 419.
hematocele are cured, the parts regaining their normal condition with the exception of the obliteration of the cavity of the tunica vaginalis.

The varicose condition of the veins of the scrotum, which is called Varicocele or Circocele, requires no particular notice here, excepting that the method of obliterating the veins with needles, as described at p. 376, may be of service in those instances where active interference is deemed requisite. The introduction of metallic or silken threads among the veins, of heated wires, or the application of pressure by means of forceps as recommended by Breschet, may each be resorted to without much danger. But the instances are rare wherein a judicious surgeon would interfere, for cold bathing night and morning, a suspensory bandage, refraining from violent exertions, with due attention to the bowels, usually constitute the routine of such practice as may be necessary in these cases. In one instance, where the patient urged me to perform castration, I used a heated awl instead, thrust it into the varicose plexus, and thus produced such a degree of inflammation as to obliterate the veins, and occasion a complete cure, while the testicle remained entire. The needle and thread, however, I infinitely prefer, as a safer and equally efficacious means of cure, and having had many opportunities of testing the practice, I can speak from personal experience as to its efficiency when radical interference seems necessary. Sketch 420 represents the appearance of the parts in one of these cases some days after the needles and threads had been applied. The fullness and roundness on this side of the scrotum being the speedy effects of the inflammation induced by these agents.

Occasionally large sarcomatous tumours of the scrotum (sarcocele, phantiasis) require the use of the knife, but such swellings are of rare occurrence in the natives of Great Britain. The largest case of the kind successfully treated in this country (weighing 44 pounds) occurred to Mr. Liston, in the early years of his practice in Edinburgh. When such tumours are only a few pounds in weight, undoubtedly the incisions should be made in such a way as to preserve both testicles and penis, for in such instances these are invariably in a sound condition; but when the growths are large—say forty, sixty, or one hundred pounds in weight, as the immediate safety of the patient is implicated, I imagine that the surgeon does wrong in attempting to save them by any protracted dissections. When once the knife is applied in such examples, the operation should be done not so much with a view of clearing and preserving these organs, as that of saving the patient from exhaustion, which, in my opinion, is likely
to be of more serious import than any shock resulting from the speedy accomplishment of the proceedings. Possibly had Mr. Key, in his operation on Hoo Loo, removed the enormous mass (56 pounds) with less regard for the genitals, the fatal shock might not have occurred; and, contrasting the proceeding (which occupied one hour and forty-four minutes) with the more rapid one by Mr. Liston, who, perceiving the emergency, swept all away at once in the course of a few minutes, it appears to me not unreasonable to suppose, that if the patient had been a shorter time on the operating table, the result might have been different.

A most ingenious plan to avoid the loss of much blood on such occasions was adopted by Mr. J. M. O’Ferrall, of Dublin, who, in removing a large tumour of the kind, had the mass held above the level of the patient’s body for some time previous to commencing the incisions. The case is otherwise interesting, and the particulars will be found in the first number of the Dublin Hospital Gazette, 15th February, 1815.

It was a source of regret to Larrey, when he was obliged to leave Egypt suddenly, that he thereby lost the opportunity of operating on cases of this kind, which seem to be common in that country. My friend, Mr. Farquhar, who was for nearly ten years in practice in Alexandria, operated with success on several such tumours; and my former friend and class-fellow, the late Dr. Esdaile, of the H. E. I. Company’s service, had many remarkable and interesting operations of the kind. Unfortunately, however, Dr. Esdaile’s surgical proceedings were so involved with the subject of Mesmerism, that less attention has been paid to them than would otherwise, I am convinced, have been the case.

Since the date of the last edition of this work our experience of these tumours has largely increased, owing to the energy of many of our brethren serving in the Eastern Empire, and few have distinguished themselves more in this respect than the late Dr. Ballingall, of Bombay. Before leaving India he related the experience of upwards of twenty cases, and the success had been remarkable—such as rarely follows most of the great operations of surgery when performed on natives in his own country. The largest I have ever operated on myself was on an Englishman, who had resided in England all his life. It weighed after operation close upon six pounds. The genitals were preserved, and all did well. The particulars were published in the Lancet for 28th September, 1861, and not long since I met this man in perfect health. Some years ago I saw Mr. Curling remove one nearly of the same size, from a gentleman from Surinam. The result was equally satisfactory. The particulars of this case were published by Mr. Curling, in the third edition of his work on Diseases of the Testis. But the most exciting instance of the kind which has occurred in this country since Mr. Liston’s, happened in the practice of my friend, Dr. Wiblin, of Southampton. The tumour was in a native of England, about forty years of age. It weighed, when removed, nearly thirty pounds. Figure 421 gives an illustration of its magnitude. The patient un-
Fortunately died soon after the operation. An interesting account of this case, with sundry illustrations, was published from the pen of Dr. Wiblin in the Transactions of the Medico-Chirurgical Society, for 1863.

No set rules can be given for the performance of such operations different from those which guide the surgeon in the removal of tumours on other parts, neither does it appear necessary here to refer particularly to the dissections which are occasionally required for the separation of those warty excrescences or cancerous ulcers, which constitute the disease termed Chimney-sweeper's Cancer. The general rules applicable in all instances of malignant disease are peculiarly so in these last-named cases, for unless the affection be removed at an early period, and also with free incisions in the surrounding healthy textures, there will be little benefit in resorting to an operation at all. I may add, however, that here, as in other parts, I have occasionally seen great relief result from the removal by the knife of a foul ulcerated surface, which has been succeeded by a seemingly healthy, though temporary, granulating sore.

The testicle itself is the seat of various kinds of swellings. That particular form of tumour termed hernia humoralis requires some separate notice. Here the enlargement is entirely the result of inflammation of the organ, and should in general, in my opinion, be treated in accordance with the usual surgical means of subduing severe and acute local inflammation. Rest, leeches, anodyne fomentations, laxatives, and low diet, are such as I should recommend; and here, too, the young practitioner should never lose sight of the value of good position. If he is careless in this respect the enlarged organ by its increased weight drops between the thighs, and the swelling is thus apt to become more troublesome, as has already been explained at p. 75, in the Chapter on Effusion. A suspender is of great value in such cases; indeed, it is well to recommend one in any instance where there may be reason to apprehend swelled testicle coming on,—as in puncturing the scrotum for hydrocele, or in the acute stages of gonorrhoea. Even in the after-treatment of lithotomy I have known suspension of the testicles of service, for in some individuals the inflammation following the wound in the neck of the bladder (probably from its proximity to the seminal ducts and vasa deferentia) appears to induce a similar action within
the gland. This result has been particularly referred to by Mr. B. Bell, in whose practice it seems to have been common.

Compression by straps of adhesive plaster, as recommended by Fricke, Ricord, and others, may be of much advantage. The same reasons that would induce me to object to the application of pressure in erysipelatous and other swellings during the acute stages of inflammation, would actuate my course of treatment in hernia humoralis; but towards the latter stages, when the swelling assumes a chronic condition, I deem the method of great value, and here the plaster or the straps may be of the ordinary adhesive kind, or such as may produce a greater excitement on the surface,—as the camphorated mercurial plaster which, in other parts of the body, is so beneficial in promoting absorption of indolent swellings. Having tried this method frequently in chronic stages of the disease, I can bear testimony to its great efficacy, for the swelling certainly disappears more rapidly than under any other treatment. In Mr. Acton's work on Venereal Diseases there is a drawing illustrative of the mode in which the scrotum should be enveloped by such straps: the process is by no means difficult, nor does it signify much as to the symmetrical arrangement of the different straps, the main feature being to keep equal pressure on all sides. The adhesive material may be spread upon chamois or kid leather, or un-glazed calico, of which slips should be cut about six or eight inches in length and half an inch wide, in proportion to the bulk of the swelling. When about to be applied the scrotum should be shaved, and then, the skin being made tight by grasping the cord, so as, in a manner, to isolate the swelling from the opposite testicle, a strap should be made to encircle the mass in any convenient direction; next another should be applied, and another again; and so on until the whole is equally enclosed. There is no need for adhering to any set plan: in one instance it will be most suitable to bring the slip down on one side and up on the other; in another, an oblique line will be best, and sometimes, again, a circular turn will be of service.

It is seldom that inflammation in these cases runs to suppuration: occasionally, however, it does, or sometimes abscesses form in the substance of the testicle without the whole organ being affected with inflammatory action. These abscesses must be treated like similar diseases in other parts of the body. It will often be found, however, that sinuses form, and that they heal up slowly. These may, in some instances, be closed by the judicious use of injections, ointments, and pressure: but sometimes they resist such treatment, and then the knife may probably be required. I need scarcely caution young surgeons against cutting freely in this organ; but that is rarely, if ever, required; for in such instances the most that may be necessary will be a free external wound in the scrotum, to permit the proper dressings to be applied to the bottom of the sinus. In some instances, however, I have seen great advantage result from a free opening of the testis in chronic sinus.

The condition familiarly known under the name of Fungus of the Testicle has usually been treated as fungus is in other parts of the
THE CHEST, ABDOMEN, AND PELVIS.

body, either by escharotics or by partial removal with cutting instruments, as first carefully described by Lawrence in 1808. Under the impression, too, that the whole organ in such cases is contaminated or destroyed, it has sometimes been removed at once. But a proposal has been made by Mr Syme, which, coming from such an authority, seems to me to deserve the attention of the profession. Mr. Syme, entertaining the idea that the fungoid-looking mass is only a kind of hernia of the tubular part of the organ, projected through an ulcerated opening in the tunica vaginalis, instead of shaving it off, has elevated the integument in the immediate vicinity of the open sore, and effected union across the surface of the excrescence. A healthy cicatrix has been the result, the swelling has been diminished to the natural size, or even less, and the alarming condition has thus been cured, while the testicle has been preserved. Mr. Syme's views were first published in the January number of Cormack's Journal for 1845, and shortly after an interesting case occurred in the practice of the late Dr. Duncan, where the patient, having his only testicle (the other having been lost previously) treated in this way, was satisfied it was preserved in all its integrity and usefulness. Mr. Holmes Coote, who has had the great advantage of seeing much of the practice of Sir William Lawrence, published some observations on this subject in the Medical Times for the 6th of July, 1850. He doubts the integrity of the testicle after the disease alluded to has been present. Mr. Syme adduced his own opinion, and the testimony of Dr. Duncan's patient gives it high legal and moral influence, while Mr. Coote offers his personal view aided by the evidence of the microscope. I doubt if physiologists have sufficient data to decide on such an important subject; and as it is well known how difficult the medico-legal features of such a question are, the subject will doubtless be of great interest to practitioners with the "long-robe" on some future occasion. In many trials which I have made of this practice, I have been favourably impressed regarding it, but I have not as yet had any special evidence as to the after condition of the testis. My impression is that hospital surgeons have paid less attention to this subject than it deserves.

In some instances hernia humoralis ends in chronic enlargement of the testicle, which may resist all the usual modes of inducing absorption: sometimes it seems the commencement of new action in the organ, whereby it is converted into a mass, to which the term "tumour" is more strictly applicable. At last it becomes evident that the natural structure cannot be saved or restored, and the removal of the disease becomes advisable or absolutely necessary. I may here also advert to the value of time and the necessity for not resorting to early operation. I have seen swelling disappear when all hope had been given up, and I have known swelling remain for forty years, without the patient (father of a large family) being in any way annoyed.

Such a case will probably present the usual characters of simple sarcoma; but many other kinds of tumours are met with in this locality. Most of them involve the substance of the testicle, and the surgeon's skill is displayed in deciding upon the nature and treatment
of such cases. I may here refer to the Chapter on Tumours in the first section of this work, to that on Diseases of the Mamma, and to the Chapter on the Surgery of the present section for further illustrations on such interesting matters. In many such cases even the most skilful may be at a loss, or possibly in error, and wherever there is doubt it is well to make some exploratory puncture with a grooved needle (p. 79), or with the scalpel or bistoury with which the surgeon may be about to operate for the removal of the mass. In most of the instances where I have seen this practice followed, the doubt which may have been on the surgeon’s mind has been dispelled, and he has proceeded with the operation; but it has happened that in some instances the too rapid use of the knife has sacrificed a healthy testicle. The case of hematocele gives a good illustration of the propriety of this cautious mode of procedure, for it has often happened that the surgeon has removed the testicle in such cases where it ought to have been left; and very recently in my own practice I have had a good proof of the advantage of the cautious procedure which is here recommended. In removing a large tumour from the serotum, weighing between three and four pounds, being doubtful of its nature, I used the knife cautiously at first, and finding the testicle healthy at the lower end of the mass, was enabled to save it. In this instance, although the testicle when left appeared perfectly healthy, cystic sarcoma came on, and about three years after I had to remove the organ when converted into a mass weighing several pounds.

The operation of castration may be done thus:—The patient should be laid on his back, and the surgeon should grasp the organ in his left hand—supposing it to be about the size of a large pear or a pine-apple—and by means of the thumb and fingers should render the skin in front tense: with a scalpel or bistoury he should then make a straight incision from the upper end of the testicle to within a little of its lower extremity: still squeezing with his left hand, and applying the point of the knife to the loose cellular tissue between the skin and the tumour, the latter will in a manner start from its place, when by dividing some loose textures behind, and cutting across the spermatic cord, the removal is completed. Before severing the latter part it is customary to desire an assistant to grasp it so that it may not retract within the inguinal canal. In general, I believe that this is a useless precaution: the cremaster is invariably excited to action thereby, and it often happens that the cord is forcibly pulled from between the fingers, which at this time, from the slippery state of the surface, have no great power to hold fast. This has occurred repeatedly in my own practice, but I have never had the least trouble in securing the spermatic arteries—for in this situation there are generally two branches. I can imagine some instances, however, when, from these vessels having passed within the canal, some difficulty might be experienced in laying hold of them,—indeed, I know of one case of the kind: The operator had to pursue them into the canal; and whether it was from this additional injury in the proximity of the peritoneum, or from other causes, inflammation within the abdomen ensued, and carried the
patient off within three days. In a case where it was necessary to divide the parts close to the lower orifice of the inguinal canal, I cut across and secured the spermatic artery before severing the whole of the cord. I was so well pleased with this manoeuvre that I strongly recommend it, in instances where trouble is anticipated, in preference to any other mode that I am acquainted with for retaining a command on the cord until the main arteries are secured. In one example of large tumour, which extended up the inguinal canal, I divided the spermatic artery nearly on a level with the peritoneum; the opening in the fascia transversalis was quite distinct, and so was the peritoneum, but the artery was easily secured, and there was no after mischief. Besides the spermatic branches, other small arterial twigs require ligature on these occasions; the scrotal arteries from the perineum and from the femoral should all be carefully secured, for, if they are not, hemorrhage is very likely to occur within the first few hours, and although it is seldom to such an extent as to cause alarm from loss of blood it may, nevertheless, occasion the separation of the surfaces, and retard the cure. I have, however, seen one instance of death resulting from hemorrhage after this operation. The instance was in a child, and the effused blood accumulated in the course of the spermatic cord as high as the spinal column, while there was no external loss. I need scarcely add that, in accordance with what may be called a characteristic feature of British surgery, as also from deeming it the best method of dressing, I recommend that the surfaces should be laid together, so as to encourage union by the first intention, and that the wound should be in other respects treated according to the principles laid down in the early part of this volume.

If the tumour is of great size, it may perhaps be proper to remove a portion of skin by an elliptical incision, but in general I prefer leaving all the skin, for it soon contracts so perfectly that there seems no redundancy whatever. In instances where the growth is large, and of course heavy, the left hand can scarcely be used with full effect in the manner above recommended. An assistant may hold the testicle, while the surgeon seizes the lips of the wound with his fingers or forceps; the assistant may perform the latter duty; or possibly, to facilitate proceedings, it may be advisable to sling the mass from the top of the bed, as was done by Dr. Esdaile, in one of the instances already referred to (p. 671), where he removed a growth in this locality upwards of eighty pounds in weight,—rather too large a mass for either surgeon or assistants to move readily without such an ingenious device. Instead of dividing the cord as the last step, some do so at an earlier stage;—but all these matters may be left to the discretion of the operator.

The narrow condition of the orifice of the prepuce, constituting what is generally termed phymosis, and often also occasioning paraphymosis, demands more attention from the surgeon than is usually bestowed upon it. In early age, in middle life, and in advanced years, it may be, and frequently is, the cause of much annoyance and distress. In some children where the prepuce is very long, the urine does not
always escape freely, and either from this circumstance, or other less apparent sources of irritation, inflammation and suppuration ensue, and acute pain when voiding urine is experienced. In some such instances I have known suspicions of gonorrhœa entertained, without any just cause. Under such circumstances the disease may be checked and cured by injections beneath the foreskin, first of tepid, and latterly of cold water; but it may happen, as the result of such an inflammation, that the foreskin becomes adherent to a large portion of the glans. From time to time the child may suffer in this way. Perhaps as he grows up, the foreskin may be drawn back over the corona, and cannot readily be pushed forward again, and thus paraphymosis is established. Then, possibly, in manhood, without this latter condition having ever been present, a venereal affection,—gonorrhœa, chancres,—even simple excoriations, may induce great swelling of the prepuce, with additional tightness of the orifice, and thus obstruct the efficient use of lotions and dressings. Even without any such causes as those alluded to, the natural discharges, from being pent up, act as irritants; warts often form within the prepuce in such cases, and occasionally a foul discharge ensues, the part becomes swollen, and when an examination is made of the narrow orifice, the interior is found to be covered with such a crop of warts as to appear like so much cauliflower. These excrescences are more frequently seen in those with the prepuce in this state than when the orifice is of sufficient size to permit free ablutions.

The most efficient relief for all these evils is to enlarge the orifice, or remove the prepuce entirely. If the latter be inflamed, unless there is reason to suspect mischief underneath, it is best to treat the inflammation merely, and to leave any such proceeding until the parts have in a manner resumed their original condition. If paraphymosis be present, an attempt must be made by compressing the glans—which in some such cases is remarkably turgid—to bring the skin forward. If inflammation has fairly set in, however, this can scarcely be accomplished, and in some of these instances the retracted foreskin often becomes so edematous that punctures will be advisable to permit the escape of serum, and it may also be necessary to carry the knife deep behind the corona, to divide and enlarge the orifice of the prepuce, which is displaced in this situation.

In gonorrhœa, or when chancres are present, when the foreskin is swollen, it is a common custom with some to slit it open, but in general I should dissuade from such practice, which in nowise expedites the cure, but causes additional pain at the time, and often increases the amount of inflammation, inducing effusion of lymph, and that condition usually termed solidœdema.

Supposing little or no inflammation present, and that it is deemed requisite to remove the extremity of the prepuce, the following proceeding will answer well:—The extremity of the foreskin should be seized between the forefinger and thumb of the left hand, and half an inch of it removed with a single stroke of a sharp bistoury—care being taken not to injure the point of the glans: the skin will now retract suddenly over half the latter part, and a large wound will appear: but
as yet the surface of the glans will be as completely covered as ever: now, the blunt-pointed blade of the surgical scissors (p. 35) should be inserted between the glans and what covers it, which is in fact the lining membrane of the prepuce, and a slit should be made half an inch, or a little more, directly upwards, and in the mesial line, when the membrane will curl over in a manner, and follow the course of the skin, whereby the glans will be completely exposed: next the skin and mucous membrane should be tacked together by a few stitches of interrupted suture,—no heed being taken of the sharp corners of the mucous tissue, excepting to keep them as far from each other as possible; the narrow circular line of wound will close by the first intention; and thus in the course of a few weeks the parts will be as if no operation had ever been performed, or rather, as if they had been naturally well formed at first.

The above proceeding may be modified in various ways: with the exception of the stitches, it resembles, I believe, the Jewish rite. In the infant the stitches are of no consequence, but in the adult I deem them an essential appendage of good surgery. Erections are of frequent occurrence during the nights immediately succeeding such an operation, and if the two membranes of the prepuce are not thus held together, a large open granulating surface will be established, which will be slow in healing, and may, moreover, by its contractions in a circular direction, cause for a long period afterwards a degree of inconvenient tightness on the end of the corpus cavernosum.

Often, when I mean to perform complete circumcision, I pass a director between the front of the glans and the foreskin as high as possible, then run a narrow, straight, sharp-pointed bistoury upon the groove, transfix the root of the prepuce by cutting towards myself, and next by carrying the blade in a circular direction, right and left, separate the part. Thereafter I stitch the mucous membrane and skin together at the margin.

In certain cases the prepuce is of natural length and appearance in every respect, saving that the orifice is remarkably tight and liable to slight cracks and lacerations. The latter condition is often completely remedied by warm lotions and abstaining from any cause of irritation; but frequently in these instances the surgeon may confer great benefit by enlarging the opening. Here it has been recommended to cut at various parts of its circumference; many good authorities advising a slit on one side of the frænum; but after trying them all repeatedly, I give a decided preference to the following: The point of a director should be pushed in front, between the glans and prepuce, about half an inch up, and then a bistoury, such as that described for the last operation, should be thrust through, from within outwards, and carried downwards, by which means a wound half an inch in length, as here represented, will be made in the skin (fig. 422):
that in the mucous membrane will scarcely appear so long—it should be lengthened with the scissors, then by two, three, or four stitches, the skin and mucous membrane must be joined, and when union is complete the orifice will be sufficient to permit the foreskin to move over the glans, as in a natural condition. Here I consider the stitches even more necessary than in circumcision: if, for instance, the wound is left to itself, a considerable granulating surface is established, and as it contracts it diminishes on all sides, and the orifice becomes nearly as tight as if nothing had been done; nay, it is positively in a more troublesome state, for the cicatrix is, perhaps, less extensible than the natural orifice, and the patient is left in a condition similar to that of one who has had a large chancre on the part; whereas, by using the needle and thread the two sides are laid together, a transverse line ofunion of an inch in length is thus secured, and the aperture of the foreskin is increased in proportion similar to that of the circumference of a circle to its radius.

Some surgeons, instead of cutting a small wound and managing it in the manner described, occasionally notch the orifice of the foreskin at one or both sides of the frenum, or to make sure that the wounds will never contract, so that the patient may not be further troubled, divide the skin and mucous membrane as high as the corona glandis;—a most gratuitous use of the knife, and in my opinion totally unnecessary. It is in such a case that the annoying results of the operation for phymosis are most conspicuous. The extent of the wound induces considerable inflammation; solidœdema of the two flaps, or wings as they may be called, often ensues; and whether swelling be present or not, the condition eventually causes so much trouble as to incline the patient to submit to the removal of such useless appendages. When the foreskin is thus extensively slit up, as may be required in instances of deep-seated chancre—it should invariably be separated at the time by circumcision.

Bleeding is seldom troublesome in these operations—if the frenum is divided near the penis, it often is free, and occasionally one or two ligatures may be required; but when stitches are used, ligatures are seldom needed. Œdema readily takes place in the foreskin, and often causes anxiety to the patient or parents. To prevent this I generally wrap a bit of thin calico around the end of the penis, taking care to have the orifice of the urethra free, and do not remove it for six or eight days, unless there be absolute necessity.

I have had to operate both on the child and the adult for adhesion between the foreskin and glans, and have generally removed the former entirely. Sometimes a dissection has been necessary to separate them; but in other instances the adhesion may be torn by stripping the skin backwards.

In many of these cases I deem it the duty of a surgeon to recommend an operation at an early and favourable opportunity, as the patient may be thus saved from much after distress. Most practitioners must have seen extensive ulceration and sloughing in some such instances during venereal inflammations. In one the glans
appears through a slough at the root and upper part of the foreskin, whose natural orifice is thus carried below the penis; in another, one half or more of the glans suffers (ulcerates—sloughs) ere the mischief is suspected, and it is a current doctrine, that, independent of venereal affections, the extremity of the organ, from never being thoroughly cleansed, is in some degree predisposed to scirrhous or cancerous action. I have myself seen several instances where the end of the penis was amputated in consequence of malignant looking tumours having their origin evidently from this condition of the foreskin. In the present time there need be the less hesitation in recommending such proceedings, as chloroform arrests much of the horrors of ancient surgery in such cases.

Amputation of the end of the penis may be done in the following manner:—The part to be removed should be grasped in the left hand, when the surgeon, with a stout bistoury or small catlin, should effect the separation with one stroke of the blade. An assistant may have hold of the root of the organ, and can restrain the hemorrhage by pressure, until ligatures are placed upon the dorsal arteries, those in the corpus cavernosum, and such others as may require them. The wound will heal by granulation, and towards the latter part of the treatment some attention may be necessary, by the introduction of bougies, to keep the orifice of the urethra open, as it has a great tendency to contract. To obviate this annoyance it suits well to slit the urethra half an inch backwards, skin and all, and introduce a stitch on each side so as to procure union. The orifice always remains of good size after this. There is no occasion to preserve the skin by drawing it upwards before the incision is made: even when it is drawn towards the diseased part, as is sometimes done, there is always a sufficiency to cover the cut surface, for the corpus cavernosum retracts greatly as soon as it is divided. I have seen this operation performed many times in the manner above described, having operated on a majority of these occasions myself. I know of no amputation which has been more successful in its primary result, but in general in cancerous-looking affections, the disease has returned either in the organ, or more frequently in the glands of the groin, and ultimately destroyed the patient.

There are few sufferers who will not give a willing assent to conservative surgery in this member, and it is my firm opinion that more may be done here than many imagine. If certain sores, which may be termed pseudo-cancerous, were treated by excision at an early date, instead of improperly directed constitutional means, there would be a better account of these diseases of the penis than surgery can at present boast of. I have myself seen some admirable results from excisions—longitudinal amputations as they might be called—of the glans penis, and if one side of this portion of the organ can be preserved, the result may be even more agreeable to the patient than to the disciple of conservative surgery.

Male infants are sometimes born with remarkable irregularities of the urinary genital organs, some of which, being such that surgery
AMPUTATION OF PENIS.

cannot amend, need no particular notice here, while others are especially worthy of the surgeon's attention.

The external end of the urethra, instead of opening at the glans, as in the normal condition, may terminate at some intermediate point between the end of the penis and the neck of the bladder. The condition is usually called hypospadias. The external orifice may be at the bottom of a wide and deep gap, between the testicles; and these, usually imperfectly developed, may, covered with skin, so resemble the external labia and vulva as to give rise to the popular idea that such a person is an hermaphrodite, or at any rate a female. The scrotum may be entire, and the passage may terminate a little in front; but the most common instances are those where the orifice is near, or within an inch of its natural place. I believe that there are more of these cases than is generally imagined, as it is mostly by chance that the surgeon sees them. Occasionally he is consulted by the parents during the early years of the child. This may be as to the procreative powers in after life, or possibly from some irritation at the time. The orifice, which is generally a slit in the skin not readily detected at a glance, is sometimes very small, and obstructs the free passage of the urine, and often in these cases, even when there is a large orifice, there is a remarkable degree of irritability about the whole urethra and bladder. In most of these cases the foreskin is defective, the glans small, the penis imperfectly developed, and often there is a particular and characteristic curve downwards, as if from want of development in the frenum.

One of these cases was specially interesting. A handsome youthful couple had no children, and the husband attributed this to such a defect. I told him my opinion that this was not the cause. He desired an operation, however, and although warned regarding the probability of failure, it was performed. It did not succeed, greatly to his disappointment, but I encouraged him to hope, and about twelve months after received a note stating that his wife had presented him with twins.

In the adult, stricture of the urethra is not an unusual complication. The instances most frequently under the surgeon's notice are in those who are married and do not beget children. Naturally this condition is considered the cause. The person may be conscious of "manly vigour," but he supposes the fault to be the defective length of the urethra. I have often been consulted under such circumstances, but have had my doubts as to this being the true cause. I knew an instance where the urethra terminated fully an inch behind the glans, and the person was the father of a fine family. I have seen another of a similar kind, where the man was childless, yet he was stout and able-bodied, and as a sort of proof that this could not be the cause, he stated that his father's parts were formed exactly in the same way. In many instances there is no need for interference. When there is a small orifice, it may be slit up with advantage, care being taken during the dressing to keep the wound from closing again. For this purpose I have sometimes, as in amputation, stitched the skin and mucous membrane together on both sides of the slit. I have
repeatedly tried to lengthen the canal in some of these cases, but although I have succeeded admirably at the time, I have always been foiled in securing the permanent effect. Generally in such a proceeding I have brought the skin on each side of the deficiency, where there is a furrow in the lower part of the penis, round a catheter, and united the two flaps by suture, but satisfactory union has never taken place.

I have met with one instance of analogous malformation, where there seemed to be a kind of double urethra. One in the natural situation was in most respects perfect, but there was a canal leading from its membranous portion which opened just behind the scrotum, and through which urine, and occasionally semen, were wont to pass. Various attempts had been made to close this passage by caustics and actual cautery, but without success: I dissected the whole tube out, and to all appearance made a cure. Such however was probably not the case, for seven years after this patient consulted me for fistula in perineum. I found a large pouch in the perineum, and in it a mucous-looking membrane, doubtless an expansion of some portion of the original tube which had been left at the operation. Chronic disease of the neck of the bladder had now set in, and some years afterwards the patient died from protracted suffering.

The case where the orifice of the urethra terminates on the upper part of the penis, named epispadias, is happily of rarer occurrence. Usually it is complicated with defects in the front of the pelvis and bladder, and such malformations have heretofore been deemed beyond the reach of curative surgery. Sometimes it appears as if only the back part of the bladder, about where the ureters open, is present. The distress in some such cases, from the mucous surface and the dribbling of water from the ends of the ureters, is often great. Mr. Simon, of St. Thomas's Hospital, has proposed to turn the lower ends of the ureters in these instances into the rectum, and succeeded in doing so on a patient under his care; but a similar operation, performed by Mr. Loyd at St. Bartholomew's, proved fatal, from injury to the peritoneum; and from a dissected specimen brought under my notice by Mr. Wiblin of Southampton, I fear that such an injury and result would too probably happen in any future proceedings of the kind.

Mr. T. Holmes of St. George's, and Mr. Wood of King's College, have done more operative work in such cases than any others I know of, and an interesting paper on the subject by the latter has appeared in the Transactions of the Medico-Chirurgical Society for 1869. He dissects flaps of skin from the vicinity, turns them over the surface and unites them in the middle so that only a small surface or opening is left, which can be readily covered by a convenient apparatus for retaining urine.

I have seen one instance of epispadias in the adult where the penis seemed of its ordinary size in all respects; but it was fairly split in two, and the portions of the corpus cavernosum were held together solely by the lower part of the urethra. The gap or fissure above, which extended from the angle of the pubes to the distal end of the glans, could be held open or closed at will. In the latter condition, the
penis seemed in its ordinary appearance. I thought in this case that by paring the thin skin or mucous membrane off the upper parts of the fissure, and bringing the raw surfaces together, union might have taken place, and a good result would have followed, but the person was not disposed to submit to any operation.

CHAPTER VI.

INTRODUCTION OF INSTRUMENTS INTO THE URETHRA AND BLADDER—RETENTION OF URINE.—STRUCTURES.

The various causes which may retard or prevent the flow of urine from the bladder need no special notice here, and a slight knowledge of surgery will enable any one to appreciate readily the most ordinary. The treatment of many of these cases, however, calls for the utmost amount of surgical ability, and even the most experienced may feel great anxiety on such occasions, for their best efforts may be baffled. There are few cases in surgery which more thoroughly try the qualities of the surgeon as to knowledge, dexterity, judgment, and forbearing patience.

The introduction of instruments into the bladder being so frequently required on the living body, should be carefully studied on the subject; and in the dissecting-room many valuable opportunities are lost of acquiring both knowledge and dexterity in such proceedings. A catheter, bougie, and sound should invariably be used in the dissection of the male pelvis. One or other, or all three successively, should be introduced previous to dissection; and when, in dissection, the lateral view of the pelvis is under notice, each instrument should again be passed, and its progress through every portion of the urethra carefully observed. Besides those of the usual curve (afterwards noticed), a straight instrument should be introduced, when, with a little management in depressing the handle, the point thus elevated will glide along almost as readily as that of one with a curve. It seems sufficiently strange that the possibility of introducing a straight instrument into the bladder should not have been perceived until the fact was demonstrated by Gruithuisen little more than fifty years ago. The idea appears always to have prevailed that, as the urethra is naturally tortuous, a bent instrument was absolutely necessary to permit its point to pass along, while the flexible nature of the materials composing the tube was overlooked, as also the circumstance that when the curve was fairly within the bladder the tube was actually on the straight part of the instrument. The student, with the urethra before him—either in the pelvis, and therefore attached to the bones and almost in its natural condition, or separated—should, by introducing straight instruments, and others
with different degrees of curve, satisfy himself of the fact that it may be made to assume almost any shape from a right angle to a straight line. These remarks are only applied to the healthy passage, however, for it does happen in disease that the canal assumes certain curves which even a solid rod of steel will not alter:—for example, in persons advanced in life, the prostate gland occasionally becomes so much enlarged, and that portion of the urethra within it so greatly increased in length, and bent at the same time, that it cannot be made straight excepting with considerable force, which is generally accompanied with great pain.

Notwithstanding that a straight instrument may be introduced readily into the bladder when all the structures are healthy, inflexible catheters or bougies should always, in my opinion, be curved near the point, as they thus more resemble the ordinary natural curve of the urethra near its vesical extremity, and probably glide more readily into the bladder, after which the straight part can be freely carried along the most fixed and least flexible portion of the tube. If a catheter is to be used, such a bend as that here exhibited (fig. 423) will generally be found most useful. The instrument for ordinary purposes should be made of silver, sufficiently stout to resist moderate force, about the diameter of a goosequill, nine inches long, and having apertures on the sides such as are exhibited in the drawing. Some prefer the small holes, others the large one, and a third party combine the two. The small openings are said to clog up, the large one to permit its margins to injure the mucous membrane,—both of which objections have attracted more notice, perhaps, than they really deserve. The point of the instrument should be slightly conical—it is generally too abrupt—and the rings at the other end are intended to give attachment to tapes for the purpose of retaining it in the bladder should that be necessary.

For many years I have preferred catheters of this shape (fig. 424),
INTRODUCTION OF THE CATHETER.

the curve near the rings being convenient for the discharge of urine into a dish, as a patient is recumbent.

Supposing catheterism to be required on the living body, the proceeding may be accomplished thus:—The patient being laid on a low bed, couch, or on the floor, with his shoulders and knees slightly raised, the surgeon, standing on his left side, should seize the glans with the forefinger and thumb of the left hand, and squeeze it gently from before backwards, so as to open the orifice of the urethra; then with his right hand he should introduce the point of the catheter (previously warmed and dipped in oil) and carry it onwards with a gentle pressure—taking care to stretch the penis sufficiently to prevent the moveable part of the urethra from remaining bent or being thrown into folds, until it has reached the angle of the pubes, where the urethra perforates the triangular ligament: thus far the surgeon's right hand may have been held nearly over the anterior part of the crest of the ileum; now, however, the hold with the left hand being given up, the right should be moved into the mesial line; in other words, the instrument should be brought parallel with the linea alba; next it should be raised, and made to describe a portion of a circle, of which the catheter is as it were the radius, and then a force little more than the weight of the instrument will cause the point to glide into the bladder. In all instances, whether of a simple nature or attended with difficulty, it is a good general rule to cause the point to move along the upper surface of the urethra; i.e. that nearest the penis. When the introduction is effected, the straight part of the catheter and the penis are nearly parallel with the thighs. Just when the operation is accomplished, the thumb of the right hand should be placed on the open extremity, and kept there until a proper utensil is placed under it to receive the urine. The same manoeuvre should be attended to when it is about to be withdrawn, and thus the fluid within the tube will be prevented from escaping until its end can be put over the pot, when the air may be admitted.

Sometimes, in very corpulent individuals, or when the patient is standing—an attitude which is preferred by some—it is most convenient to introduce the point of the catheter with the right hand nearly between the patient's thighs and the convexity towards the abdomen; it is then, after being pushed along as far as the triangular ligament, turned into the same position as when the other mode is pursued, and thus carried into the bladder. This manoeuvre has been termed the "tour de maître," and was at one time more practised than it seems to be at present. It is seldom, indeed, that patients have such a protuberant belly as to render this attitude absolutely necessary, and while it is impossible to point out any peculiar advantage which the method possesses, it is not difficult to perceive many objections against it. The latest fashion in catheterism is that of introducing the instrument with one hand only: the point is passed into the orifice of the urethra, and then, by hooking the penis into a position similar to that when it is held between the fingers, partly by pushing the catheter onwards, and partly by, in a manner, shaking the organ on to the
instrument, its point reaches the triangular membrane, when it can be slid along as in the common method. This proceeding can readily be accomplished under ordinary circumstances, but it probably requires a little more dexterity than the usual one, over which, when properly performed, I am not aware of any real advantage which it possesses.

If the urethra and other parts are healthy, all these proceedings can be accomplished with the utmost facility; but there may be many difficulties to overcome, most of which demand particular notice here. In corpulent persons, with the pelvis naturally large, and the prostate much increased in size, the interior of the bladder is further from the orifice of the urethra than under ordinary circumstances: sometimes, even when the prostate is in a natural condition, the neck of the bladder is higher up during great distension of the viscus, and in either of these cases a longer catheter is required than that in common use; it may be advantageous also to have the curve somewhat larger. Sometimes when the urethra is of its full calibre, the point of the instrument is apt to hitch on that part where it passes the triangular ligament; indeed, in ordinary cases, when it does not slip readily along, this is the seat of obstruction: the operator may probably be urging it onwards a little too high, or somewhat too low, and in either instance, if only a fold of the mucous lining be in the way, it will be sufficient to foil the attempt. The occurrence is more likely with a small-sized catheter than with one above the average diameter; and in instances of paralysis of the bladder, resulting from fever, injury of the spine or pelvis, and such like cases, where the urethra is known to be free from stricture and otherwise healthy, it is well to bear this in mind. At other times, when the prostate is not greatly increased in its entire bulk, the middle lobe may be of such a size as to project right in the course of the point of the instrument; and again, the most common and most troublesome of all obstacles is stricture in the urethra, especially if previous futile attempts have been made, causing laceration, bleeding, and subsequent inflammation, infiltration, and swelling,—the latter being either the result of the inflammatory action, or possibly occasioned by the presence of blood and urine.

In elongation of the urethra, whether from enlarged prostate or retention, or in examples of paralysis with healthy urethra, there is seldom any great difficulty; a little gentle movement of the instrument will generally suffice to put its point in the right way, although in the prostatic affection this is not always readily done. Here, perhaps, the point has to be elevated over the projecting middle lobe, or made to glide along by one side or the other. In the instance of stricture it is not reasonable to suppose that the full-sized instrument above recommended can be carried along the contracted passage, and therefore one of smaller diameter must be selected, such as the small sizes represented on page 696. Catheters vary in the latter respect from that of an ordinary silver probe to about three lines, and such a size must be chosen as will pass the narrow course: the larger it is the better, for the point of a small one
PUNCTURE OF THE BLADDER.

is very apt to get out of the proper line, and thus for future attempts the difficulties are increased, by the formation of a false passage which has not penetrated into the bladder. When a small instrument is used, only the slightest imaginable force must be applied to carry it onwards; it should rather be insinuated than pushed along, and if the latter process be deemed necessary, an instrument of larger calibre should in general be selected.

In all instances of difficulty, from whatever cause it may arise, if it be about the membranous part of the urethra, the forefinger of the left hand passed into the rectum will greatly facilitate the operation. In this way the point can usually be felt, and guided in the proper course, but there are other proceedings which may be followed in cases of this kind with great advantage. Thus in some examples the instrument seems to pass more freely when the patient stands; indeed, some surgeons on all occasions prefer this attitude to the recumbent. In cases of extreme difficulty, however, and supposing the patient to be suffering under the distress of long-continued retention, the erect posture cannot be easily maintained; and there are many instances where it is not practicable. Clysters of warm water, the hip-bath, blood-letting—by lancet, leeching, or cupping, opiates, and antispasmodics, especially chloroform, may perhaps save the necessity for persevering with the catheter; the bladder may be in part or entirely relieved; if not; it may be needful to go on, and possibly, if the patient is now placed in a warm bath, the efforts with an instrument may succeed. If the surgeon is still foiled, and the urgency is great, the bladder may then be entered in any of the ways afterwards described. Unless, however, there is reason to suppose that the bladder or urethra behind the obstruction will burst ere long, the last resource of puncturing should not be hurriedly adopted. Even in the worst case of retention, when the bladder arrives at a certain point of distension, the urine generally begins to dribble away; thus further accumulation is prevented, for at this time it often happens that the secretion of the fluid goes on less rapidly than before, and although this is a condition which cannot long continue, and should not long be permitted, some favourable change may yet take place, and the patient be thereby saved from the equivocal advantage of puncturing.

I use and recommend the silver catheter, as preferable to all others, and have rarely seen an instance where a flexible gum instrument could be introduced when the other had failed; nevertheless, many excellent surgeons choose the gum catheter, which may be used by itself, or made to alter in bend at the time of the operation, by means of the iron wire with which it is usually provided. When introduced and the wire is withdrawn, it certainly, by bending to the course of the urethra, must be less likely to cause irritation than the hard and inflexible metallic instrument; and therefore in cases where there is a necessity for keeping a catheter constantly in the bladder, it should be preferred. Some patients are in a condition to walk about, although from disease of the urethra, bladder, or elsewhere, it is
necessary to retain a catheter, and here the advantage of flexible material must be sufficiently obvious.

In cases of retention of urine, when it is found that diuretics, anti-spasmodics, warm baths, &c., prove of no avail, and when, moreover, it is impossible to introduce a catheter into the bladder, in the usual manner, it may become necessary to evacuate the urine through some artificial opening into the viscus. The bladder may be punctured in a variety of ways and places. For example, if the obstruction is near the neck of the organ, the catheter may be forced along in the course of the original urethra, or as near to it as possible. Perhaps in this manner it will pass through the substance of the prostate; but this should not constitute an objection to the plan, for the new passage may in every respect be as efficient as one formed by puncture or incision in any other way. Here I beg it to be understood that it is not meant by the above recommendation to countenance the formation of what is commonly termed a "false passage"—a phrase which is generally used, to imply that the instrument has not been carried along the natural course, as might have been accomplished with greater care or greater skill. That this blunder is often committed there can be no doubt; but the above mode of procedure is advised under the supposition that the urethra has become in a manner impervious, either from stricture, or alteration in the size and shape of the prostate.

If this method is not selected, the bladder may be punctured above the pubes in the following manner:—The patient being laid on a table, with his shoulders and knees slightly raised, a trocar and canula should be thrust through the skin, fat, and linea alba an inch or two above the pubes. A puncture or slight incision with a scalpel may at choice be made, through the skin, to facilitate the entry of the trocar. The canula may be left in the wound for some days afterwards, or, in preference, a flexible gum catheter should be introduced and retained. When such a proceeding is required, the bladder will perhaps be greatly distended, and will consequently be prominent in the hypogastric region; its upper end will therefore be so far above the pubes as to have carried the peritoneum beyond risk: such a danger, however, should not be overlooked, and every care should be taken that this membrane is really above that part where the puncture is about to be made. There must be danger from the proximity of the serous surface in case of the escape of urine into the cavity, or of inflammation; but there may be equal hazard perhaps in making the puncture too close to the pubes; for as the bladder contracts, the orifice may sink so much into the pelvis that infiltration may ensue.

The bladder may be emptied through a wound in the perineum similar to that for lithotomy, afterwards described, or the incision may be conducted between the bulb of the urethra and anterior verge of the anus, or it may be thus:—A curved trocar and canula, about seven inches long, should be introduced into the rectum on the concavity of the forefinger of the right hand, the tip of which should
be placed on the triangular space behind the prostate gland; then the point of the trocar, which should have been concealed within the canula, should be pushed onwards, forced through the tunics of the rectum and bladder, and the end of the canula being continued in the same course, the former should be withdrawn, when the urine will flow through the tube. The latter must then be removed, and the fluid allowed to find its own way in future, or perhaps a small flexible catheter may be carried into the bladder, through the interior of the canula, ere it is taken away. The catheter may, however, afterwards be found inconvenient in the anus.

This drawing (fig. 425) will give an idea of the different points for puncturing here recommended: that by the rectum seems most in use, and where such a proceeding is required is, perhaps, most worthy of recommendation, being probably, while equally efficacious, less dangerous than any of the others. If the bladder be at all dilatable, the triangular space will be considerably larger than in the natural condition of the organ,—the vasa deferentia will be further apart,—the peritoneum higher; nevertheless, the proximity of these structures should be remembered, and, to avoid them, the point of the trocar should be kept about the middle of the space. If the prostate is large, as it usually is in such examples, the puncture should be made close behind,—nay, it had better be made through it, than that the peritoneum should be endangered; for although a seminal duct, or a vesicula, might thus be injured, that is of little consequence in comparison with puncture of the peritoneum, which would in all probability occasion the death of the patient.

It will be observed that, in any of the last three modes referred to, the urethra is left in the same condition as that which has given rise to the necessity for puncture. Possibly it may still continue impervious, and the urine will therefore continue to drain away through the artificial aperture. Under such an anticipation the operation above the pubes has been preferred by some, on the score that the discharge of urine may be in some measure regulated by the flexible catheter: but it really seems doubtful whether this condition, or that in which the urine collects in the lower part of the rectum, and is discharged per anum, is the least troublesome. In certain instances, recorded by Sir Everard Home and others, a catheter of full size has

\[\text{Fig. 425.}\]
been passed by the urethra within a few days of the puncture by the rectum.

Puncture by the rectum, judging from the experience of Mr. Cock, of Guy’s Hospital, as laid before the Medico-Chirurgical Society, cannot, under the circumstances requiring its performance, be called a very hazardous operation; but, for my own part, I should generally prefer the mode of forcing a passage as nearly in the original course (if not altogether so) as I could possibly manage. Doubtless, with much patience, caution, and skill, one surgeon will introduce a catheter where another has failed, and often he himself will at last succeed when he has probably been in despair: in some instances the natural tube will have been opened, but the instrument will very often have been thrust in a devious course,—sometimes only below the mucous membrane, at others through the prostate,—even through the tunics of the bladder beyond the limits of this gland. I have seen five different passages in the prostatic portion of the urethra or bladder, each capable of admitting a full-sized catheter, and which was the original urethra (if it existed at all) it was impossible to say. Here, during life, an instrument had been frequently used, and, as was supposed, with great skill and dexterity: certainly, in so far as the injuries went, the patient was none the worse, although assuredly there was no occasion for so many canals, for one would have sufficed, and the surgeon, supposing that he had been conscious of having forced a passage at first, and that with a large catheter, should have gone through the artificial course on all future occasions. If I may venture to criticise the catheterism of such surgeons as have claimed superior dexterity in this operation, I should say that occasionally they have effected this manœuvre, and led others to suppose that the instrument has been carried along the natural course. In my opinion the practice is the best that can be adopted; but, in giving it recommendation, I hope it will not be supposed that I sanction carelessness as to the danger of thus wounding the neck of the bladder. The formation of a false passage is justifiable only in extreme cases, and when all other reasonable means have failed,—and then, in my opinion, it had better be made with the catheter in the manner referred to. Neither should it be supposed that this is the easiest mode of puncturing the bladder;—on the contrary, more tact with the instrument, and a nicer knowledge of anatomy, are required to succeed in this way than in the others referred to. Very little force will thrust the point of a catheter through the membranous portion of the urethra, and cause it to pass on one or other side of the prostate; but something more is necessary to guide it in the proper course; for, even when the surgeon has all the advantage of a wound in the perineum to assist him to guide the point of a catheter into the bladder, he often finds it not such an easy task as he may probably have imagined.

Supposing that the bladder is emptied in this manner, the catheter should be allowed to remain for four, six, or eight days, when it should be withdrawn, cleaned, introduced again, and,—the same movements being repeated at proper intervals,—retained until a callous passage is formed.
Sometimes in cases of retention of urine, complicated with impassable stricture in a part of the urethra anterior to that in which the proceedings above referred to are required, it may be advisable to divide the obstruction with a knife, and thus permit the evacuation of urine and introduction of an instrument at the same time. In certain instances, especially if the stricture were supposed to be very short, if the surgeon does not wish to make way by force, the passage may be enlarged with a lancet-catheter, or other convenient instrument, but in many cases it will be necessary to make an incision from without. I have seen boys who have been severely wounded in the perineum by an earthenware pot breaking under them, in whom the urethra had been injured by the accident, and its anterior part had afterwards closed in the cicatrix. In other youths, the obstruction has been spontaneous; but such examples resulting from injury are most frequently seen in the adult, and are well known to the practical surgeon as being peculiarly obstinate to deal with by any of the ordinary modes of treatment. Sometimes the impervious condition of the passage is accompanied with fistulous openings in the perineum; in others the surface is entire, and occasionally there may actually be infiltration of urine in the cellular tissue between the skin and the neck of the bladder. In certain examples the distended urethra can be felt behind the stricture, and here there will be little difficulty in doing what is required: for, first, the bladder may at once be evacuated by cutting into the tube, and the latter being so capacious, there can be no great trouble in getting the point of a catheter along, when once it has been got through the contracted part. The proceedings may be conducted in this manner:—A catheter of nearly the natural calibre of the urethra being introduced, the patient should be fixed and placed in a similar position as for lithotomy; then the surgeon, seated as if about to perform that operation, should cut in the raphe in the line of the stricture, and having made an incision through this part into its centre, about an inch or somewhat more in length, in accordance with the supposed length of the obstruction, should feel for the end of the catheter, which should now be carried along the posterior portion of the urethra into the bladder; sometimes a few applications of the knife will suffice, and the instrument will slip along at once; but on other occasions the most difficult step is to get it into the back part of the canal. Perhaps the latter may not have been sufficiently opened,—if, indeed, it has been cut at all,—and possibly there may be stricture so far along, that the difficulty may still be as great as if an attempt was being made to free the passage without any wound in the perineum. A director or a straight staff passed through the external wound into the back part of the urethra may probably be of some advantage, and supposing that the catheter is at last introduced, it must be kept in the bladder (changing it from time to time) until the wound in the perineum has nearly closed.

In this operation, as well as in that previously described, a catheter about the medium size (No. 6 or 8) and length should be used. Occasionally, if the pelvis is big, the patient stout, and the prostate...
large, an instrument an inch or two longer than common must be used, and it should always be sufficiently stout not to yield to any reasonable amount of force. It may bend, as I have witnessed in several cases, or it might actually break. A silver instrument is generally used on these occasions, but after the canal has once been forced, a flexible catheter may be advantageously substituted in some instances. Either may be kept in the bladder by means of tapes attached to the rings and fastened in front and behind to a band round the loins. Narrow slips of oiled silk or twine will perhaps answer better than common tape; and instead of fastening them directly to the instrument, it is the custom of some first to attach a circle of wood or bone to the rings, by a couple of tapes, and then, this being slid upon the penis, to connect the body tapes with it, whereby they are less apt to be disturbed.

Such proceedings as those above referred to should, in my opinion, be seldom resorted to when an instrument can, with tact and reasonable force, be pushed onwards without any external incision, and when improvement seems to follow the ordinary mode of treatment; perhaps the most legitimate cases are those where, besides the obstructed condition of the urethra, infiltration is present (a complication not unusual), or where there are fistulous openings connected with the urethra.

In instances where the urine has passed chiefly, perhaps entirely, through fistulous openings in the perineum, scrotum, or neighbouring regions, and when probably the surgeon has been repeatedly foiled in passing a catheter into the bladder, he has at last effected this by cutting in the manner above described, and ultimately cured the patient; and in retention of urine conjoined with stricture, when it has been found impossible to give relief with the catheter, the same operation has been most satisfactorily resorted to. In the cases last referred to there may or may not have been infiltration, and the surgeon has perhaps preferred this plan to that of puncturing the bladder.

I myself prefer this practice to puncturing, as, in addition to giving immediate relief, the best means under the circumstances are thus taken to cure the stricture. There may be abscess in the perineum or scrotum conjoined with stricture and fistula, or there may be suppuration and sloughing, in conjunction with stricture and retention. And in all such cases, if the surgeon resorts to the operation referred to, he may do so whilst treating the peculiar condition present. In some instances the best plan may be to give relief to the most urgent distress and delay division of the stricture, in hopes that in weeks or months the state of the patient may be more favourable for further proceedings, but as a general practice doing the whole at once will be the most efficient.

In most or all such cases it may possibly have been out of the surgeon’s power to introduce a catheter into the bladder; indeed, if the case were one simply of retention of urine with stricture, success with the catheter would in general be sufficient to settle the question of a cutting operation. The flow of urine would give the required relief,
and unless it were thought prudent to take steps to treat the stricture by division, and so avert the chances of speedy recurrence of the alarming condition, most surgeons and patients will be content with the temporary effects of the catheter. When a small instrument cannot be introduced in the ordinary way, and when it is resolved to pass one of considerable size by incision, the operator must find the interior of the canal, both in the seat of stricture and in the back part of the passage, as he best may; and here there may be extreme difficulty in effecting the satisfactory completion of the proceedings. In some instances, but certainly not in all, the vesical end of the urethra may be felt distended with urine, and here there will be little trouble, but when such guides as an instrument—however small it may be—already introduced, or a distended urethra, are not present, the facility or difficulty of the operation cannot be calculated on with certainty. In my own experience I have occasionally been astonished at the seeming simplicity of the whole proceeding, but often I have felt the circumstances equal to the most difficult I have ever experienced in this department of surgery.

I think it may not be deemed incorrect to state that these proceedings are not resorted to so much for the treatment of stricture as for the more urgent condition which may have demanded the surgeon's immediate interference. In some instances there is such an amount of local disease and continued irritation that life is hardly worth enduring: in other cases speedy death is impending unless the surgeon interferes, and if he cuts into the perineum in the mesial line, divides the stricture and introduces a full sized catheter along the whole of the urethra into the bladder, he is resorting to an old established practice of surgery which can scarcely be sufficiently praised. It confers the greatest relief on the patient, and may justly be called a triumph of surgery. It is a formidable operation, however, and as such is not free from danger. Death sometimes follows, and hence the surgeon is cautious in resorting to it, excepting in extremity. The circumstances inducing the dilemma may of themselves be the cause of death, yet possibly in such a case the operation may be blamed for the final disaster. Here, perhaps, as in the case of strangulated hernia, the operation is held as the cause of death, whilst it should in more correct terms be said that death has ensued, notwithstanding an operation. In my own practice and experience I have had and seen several fatal results from the use of the knife at a time when there was no absolute necessity for such interference, but the numbers have been few in comparison with those where the best results have followed. No one condemns lithotomy because the average of deaths is one in every five, seven, or ten of the patients so treated. Neither should the operation above referred to be condemned, because in certain instances death follows the efforts of the surgeon to relieve the patient from an otherwise hopeless state of misery.

When the urethra has been burst by external violence, or has given way behind an obstruction, and infiltration is present, there should be no hesitation about making free incisions; they will afford
the patient the only chance of life, in all probability; for although in
good constitutions recovery does take place in some, when actually the
urine has made its own way to the surface, such examples are few in
proportion to the numerous instances where death is the result of this
condition, even after free openings for the escape of urine have actually
been made. In all such cases it ought to be a rule to introduce a
catheter by the urethra into the bladder, and for this purpose an ope-
ration like that above recommended should be resorted to. Urinary
infiltration is most frequently seen in those advanced in years, and
perhaps also with otherwise debilitated constitutions: hence probably
the frequent fatal results; but even in the young the danger is immi-
nent. One of the most remarkable cases of recovery from this state
which I have ever witnessed occurred under the able management of my
friend, the late Professor Lizards, of Edinburgh, in a boy about nine
years old, who had impervious stricture (resulting from an injury of
the perineum), in whom the urethra gave way behind the obstruction.
The perineum and scrotum were much distented, and the urine had
passed in front of the pubes into the cellular tissue under the skin of
the hypogastric region; a deep wound was made on the left side of the
perineum, as if for lithotomy, up to the prostate gland, without, however,
entering its substance; the urine escaped freely, and although incisions
were also required for suppuration in each groin, above Poupart's
ligament, the boy survived, and ultimately, by attention to the urethra,a
good cure was effected. In this instance the incisions were deemed
sufficient, and no attempt was made to introduce a catheter at the time.

Occasionally in some of these cases the whole scrotum sloughs, and
the testicles (each, however, covered by the tunica vaginalis) are laid
bare. Such a condition is known sometimes to follow the operation for
hydrocele, where port wine injection has been thrown into the cellular
tissue instead of the serous cavity; and I have seen it arise from un-
healthy inflammation and sloughing after an operation for the radical
cure of varicocele with needles and threads. If the patient, being young,
survives until the sloughs begin to separate, although the result may
remain long doubtful, recovery usually takes place.

The subject of stricture in the urethra is one of great importance,
and requires, probably, more notice than the limited space of such a
work as this will admit. The frequency of the disease is such, that it
is familiar to most surgeons in practice, and there are few individual
cases in surgery which have received more particular attention. The
disease may be said to consist in a contracted or diminished calibre of
the urethra, caused by acute or chronic inflammation of the mucous
membrane, or the tissues immediately external to it. In certain
instances, particularly those of slight importance, the mucous surface
is probably entire, but in others it is the seat of ulceration—more or
less extensive in accordance with the amount of disease. The product
of the inflammatory action may occasionally be on the inner surface of
the mucous membrane, but generally it is either in its substance or on
the outer surface. Sometimes the mucous membrane alone is affected,
and occasionally the corpus cavernosum participates,—this structure
TREATMENT OF STRICTURES.

being in a manner obliterated by the lymph which is effused. Stricture may be single, and may vary in length from less than a line to several inches, and in some rare cases the greater part of the tube may be affected. In these latter cases, the calibre of the canal will vary at different parts. There may be several distinct strictures in one tube, and the intervening parts may be healthy. The disease may be in any portion of the canal, but its most common seat is where the tube is covered by the corpus spongiosum. Here, probably, the bulb or perineal portion is most frequently affected. A stricture of the membranous portion is very rare, and I have my doubts if there be such a condition as a real stricture in the prostatic part, although from disease of the prostate there may be change in the tube here, and obstructions to the flow of water or the passage of instruments.

The symptoms of stricture in the urethra are usually very palpable. Frequent desire to pass water, more or less difficulty in the process, diminution in the size and alteration in the shape of the stream—which is sometimes flat, twisted, or split into two; in some, inability to expel the last few drops, in others, constant dribbling of urine, are among the most common and conspicuous indications. In many instances such conditions remain for years without inducing the patient to consult a surgeon, but when he does so, he generally finds that he ought to have applied at a much earlier date, and is the more convinced of this when he perceives the benefit which follows judicious surgical treatment.

The effects of stricture on the constitution are usually very injurious. The disease is, more or less, a constant source of irritation. In many instances the difficulty in voiding water is extreme, particularly as the disease advances, and often there is total retention, so that the patient's condition is hazardous. Sometimes the retention seems to depend solely upon the contracted state of the canal, and often it appears to be the result of spasm. In many instances,—and this is a cause which is seldom alluded to,—I believe that the difficulty of passing the urine is from want of tone and energy in the muscular fibres of the bladder. Besides this functional derangement, the presence of stricture is apt to induce physical disease. In cases of long standing, the bladder gets thickened in its tunics—particularly the muscular, often the ureters are dilated and thickened, and at last the kidneys themselves are affected. In some instances the latter organs are symptomatically involved at a comparatively early date, and I have known a case declared, from some of the symptoms, to be stone in the kidney, which was soon after proved to be stricture in the urethra, as all the suspicious symptoms were dispelled under the ordinary surgical management of the case with bougies. In certain persons there seems a disposition to form abscess, and on such occasions there is always increased distress. The matter may burst into the urethra, or reach the cutaneous surface. In some, perhaps the inflammation is altogether irrespective of urinary infiltration, while in others, there seems every probability that a few drops or more of this fluid is the chief cause of the urgent distress. This latter condition may result from
the presence of an ulcer in or immediately posterior to the stricture, or from sudden giving way of the passage behind the disease, which permits the ready infiltration of urine throughout the cellular structure of the perineum and scrotum.

The earlier a stricture is attended to by the surgeon, the more readily will it be cured. The treatment may be said to be entirely mechanical, although in such instances the ordinary principles of surgery should not be overlooked. A little rest, a warm bath, a few leeches to the perineum, or a simple aperient, will often prove of greater service than any direct mechanical interference. In certain states of the system the most careful attention to all these points may prove of little avail, and for a time the stricture may seem to resist all interference whatever. It is curious to observe how, at other periods in the same cases, no such seeming resistance is perceptible, and it is a matter worth consideration, that in some of these all the evil symptoms wear off, and in months or years after, there is no complaint of stricture. It is probably from the observation of a few such instances, that some men, supposing themselves good surgeons, have actually advocated the treatment of stricture by means of medicine and time, the physic, of course, receiving from such quarters the chief share of approbation. Such cases are, however, only the exception to the general rule, and some mechanical mode of treatment is just as certainly required in the general and ordinary treatment of stricture, as the hands of the surgeon arc essential for the cure of stone in the bladder.

The practice of dilating stricture by means of bougies seems that by far the most generally resorted to. The catheter is by many surgeons used as a bougie in the treatment of stricture, instead of the solid iron rod which is commonly resorted to for the purpose of dilating such contractions. The mode of introducing the latter instrument is in most respects similar to that required in passing the former. Whichever is used for stricture (and in my opinion the choice may be left to the surgeon or patient), a size is selected which will pass the obstruction by gentle pressure; then in the course of two, four, or six days, a larger size is carried along, and so the process is repeated until the urethra is brought to its proper diameter. The outer lines of each of these circles (fig. 426) indicate five of the sizes commonly employed, and the smallest is about the least in diameter that I ever use, either as a catheter or bougie; but circles larger than the greatest here indicated, may be needful to bring the urethra to its natural calibre, and from twelve to fourteen instrumcuts, varying in diameter from the smallest to a much larger size than here exhibited, may be required in practice.

A stricture is not always so readily overcome as these remarks might seem to imply, and this will depend on a variety of circumstances,—as, its position, its length, its diameter and firmness, the
irritability of the canal, the sympathetic effect of each introduction on the urethra, bladder, and system generally; these, and many others which need not be particularly alluded to here, may all retard or render the cure a process of difficulty, demanding considerable care and time.

A stricture in the perineal portion of the urethra, especially near the triangular ligament, is almost invariably more troublesome to treat than one in any other site; one of half an inch, an inch, or of greater length, is usually more obstinate to deal with than when the obstruction is more limited: a close one, particularly if it be firm, as is most commonly the case, must require more frequent use of the dilators, and in some individuals the application of an instrument to the urethra produces so much pain and irritability both at the time and afterwards, that the final cure may be much retarded.

There are greater varieties in bougies than in catheters. The curve of the steel bougie is varied in accordance with the views of the surgeon, and occasionally, if the anterior end of the urethra be alone the seat of disease, a short straight rod is all that is necessary. The point is usually (and always should be, in my opinion) a little more conical than that of the catheter. Sometimes the steel is plated with silver or gilt, which is an excellent method for preventing rust. Instead of steel, some prefer a more flexible material, such as the ductile metallic composition, for the purpose of bougies,—the wax bougies, or those now formed in a variety of ways by the aid of caoutchouc. Gutta percha also has been used, and extolled as being a superior article for such instruments, but I strongly urge that it should never be chosen when other material is at hand. I have repeatedly had to extract portions of gutta percha instruments which had broken off and remained in the bladder. In one instance a stone had formed, and lithotripsy was performed,—the nucleus having been discovered only during the operation. In another, what had happened was known to both patient and surgeon. Various attempts to extract had been made before I saw the case, but these had failed. With a small lithotrite, however, I was enabled to seize and withdraw about six inches of an instrument made of this material. The silver wire, with the round knob at the point, as recommended by Sir Charles Bell, is, in so far as I know, seldom resorted to nowadays.

Various contrivances have been devised for the purpose of enlarging the urethra, differing in simplicity from that of the ancient Egyptian,—who used the gut of a small animal, which, while it was in the canal, was distended with air,—to the complicated apparatus referred to below; but most of them are of service chiefly when they are carried beyond the seat of stricture, and therefore can come into play only when the main difficulty with a stricture has been overcome,—viz., the passing an instrument at all; for when once this is accomplished, the case usually is, as it were, within the command of a bougie.

The ingenious instruments brought before the profession by Mr. Thomas Wakley, give great facility and certainty in effecting rapid
dilatation of the canal. A description of these instruments, as exhibited at the Medical Society of London in January, 1851, will be found in the first volume of The Lancet for that year, and Mr. Wakley has since published in the same journal many cases to prove their efficacy. They consist of a slender rod, or bougie, and a series of tubes or catheters. The bougie being first introduced, a small catheter, open at the point, is slid over it through the stricture, then after this a size larger can be slid along, and thus in the course of a few minutes the calibre of the urethra may be increased, so that a catheter of size six, eight, or ten may be used. This rapid distension must be managed in accordance with the seeming facility with which the stricture gives way, and generally the largest tube used at the time is of flexible material, which is pushed along, guided by the first rod, into the bladder, where it is allowed to remain as long as the patient may be able to bear it; or the surgeon chooses to keep it. If this is retained for a few days, and it is desirable to make further enlargement of the canal in the seat of disease, a rod can be passed through this tube ere it is withdrawn, and a series of larger instruments can be used as in the first proceedings. On this subject I may refer also to the lectures of Amussat (p. 110) published by Dr. Petit in 1832.

Mr. Holt, of the Westminster Hospital, has described in The Lancet (vol. i. 1852), and subsequently in a separate treatise, another mode of effecting rapid dilatation by means of a bougie constructed of two blades, which can be slightly separated from each other whilst they are within the stricture; and instruments of a similar kind are depicted in Civiale's work on this subject, published in 1849. Mr. Holt's practice with this instrument has been extensive and successful, but it is occasionally followed by fatal results. Its chief advantage seems rapidity of action, but from what I have said I am most inclined in ordinary practice to the use of simple bougies. Dr. Richardson, of Dublin, has paid special attention to this subject.

The instruments and methods of treatment last referred to imply a more or less rapid mechanical destruction of the stricture with sudden enlargement of the canal, and doubts may reasonably be entertained as to the general applicability of the practice. In the ordinary treatment of stricture by bougies, the slight pressure or stretching caused by the successively enlarged instruments is considered to induce absorption, and the successful issue of the case is attributed chiefly to this process. If it were that the contracted urethra could be enlarged to its natural diameter in one or two operations, with all the benefit resulting therefrom and no concomitant mischief, then the rapid processes of cure, above referred to, would undoubtedly be the best, but there has as yet been so little done in this way by surgeons, that few can speak from personal experience. Messrs. Wakley and Holt have published large numbers of cases to show the successful application of the instruments which they have recommended. My own impression is, that rapid enlargement of the canal by any instrument is in many instances followed by much evil. There is frequent proof of this in
TREATMENT OF STRICTURES.

the ordinary use of the bougie, and most surgeons have had reason to regret using this instrument at too brief intervals, or probably being tempted, in order to shorten the treatment, to use such a size as to require some force to get through the stricture. In these instances, violent shiverings, spasms, retention, inflammation, swelling, and threatenings of abscess in the perineum, are of common occurrence, and often, instead of a rapid cure, the successful issue of the case is greatly protracted by the accidental, or it may be intentional, use of an instrument too large for the stricture.

From the above remarks it will be readily perceived that I give preference to the bougie as a general means of treating stricture, and the plated steel rod or a silver tube is the kind which I generally use. In ordinary cases, where there is no immediate urgency for passing the instrument through the contraction or into the bladder, unless it glides readily along with a moderate force, it is better, in my opinion, to make the entry after repeated trials on different occasions, than to force it at once. Some surgeons are content for a time with the pressure of the point of a bougie upon the end of a stricture, but most prefer that the instrument should be carried through at once. Unless the circumstances are very peculiar, success in this particular may generally be attained, and, from the first attempt until the cure is complete, the surgeon must be guided as to the period of repeating his operations by the apparent effect of each: the urethra in one individual may be so callous that in eight-and-forty hours, or even less, an instrument may be again introduced, whilst in another, four, six, or eight days must be allowed to elapse. On each new occasion a larger size must be used, though from time to time, in getting from number one in the scale up to nine or twelve, it may be well to rest satisfied with one size until the urethra becomes, in a degree callous, when a larger may then be had recourse to. There cannot be any rule as to the time that a bougie should be retained in the passage. For my own part, I fancy that live or ten minutes may be best. Less will suffice in some instances, and this period or more may, in many, cause annoyance or mischief. In certain examples, keeping the catheter in the bladder for many days is productive of rapid softening in the seat of stricture and correspondingly rapid eure.

Patients usually dread the appearance of blood on the introduction of instruments, but there is seldom any real cause for apprehension,—in fact, I have often thought that those strictures which bleed readily are more susceptible of a rapid cure than others. An old, hard, tight, and callous stricture seldom bleeds on the application of any moderate force; but when the converse obtains, the weight of the hand alone on the instrument will cause hemorrhage, and in such a case, provided the bougie or catheter be properly used, the obstruction is usually overcome with comparative facility. When an instrument of tolerable size (number six or seven) can be further introduced, operations are generally accomplished without bleeding. In thus treating of hemorrhage more lightly than some may deem correct, I by no means sanction any unnecessary rudeness. There is a certain amount of
force and energy which may legitimately be resorted to by one well acquainted with the course of the canal, and well practised in the use of instruments; but the young surgeon commits a great error in the treatment of these cases if he supposes that a heavy stiff hand, and force, will compensate for that skill and tact which can only be acquired, in the course of years, by experience in the dissecting-room and on the living subject.

The method by means of cauterization has been known to the profession since the time of Paré, and though practised by Hunter, and much recommended by Home, seems to have gone almost out of date in this country. From my own experience I consider that it is, perhaps, too much neglected in the present day. I have often had occasion to observe how admirably a touch of nitrate of silver has served to allay irritation in some cases of stricture, and the potassa fusa, as first recommended by Mr. Whately, is zealously advocated by Mr. Wade in his Practical Observations on Stricture of the Urethra. The lunar caustic has probably no other effect than that just referred to, but the caustic potash, besides this, undoubtedly destroys tissue, and so permits a more rapid access along the urethra with a large instrument.

Much ingenuity has been displayed by Paré, Ducamp, Amussat, Lallemand, and others in the construction of instruments for cauterization, but a wax bougie, as recommended by Hunter, less or larger than the size here represented (fig. 427), is the most convenient way of applying either of the caustics referred to—a small portion of the material to be used being inserted on the point marked by the star in the figure. A bit of caustic a little larger than a pin’s head is usually considered sufficient for the object in view. The instrument thus prepared has been dignified with the heroic name of an “armed bougie,” and when the lunar caustic is used, a momentary touch of the stricture with the material is all that is required, but with the caustic potash a longer time is needed to let it melt, and at the same time have its due effect on the tissues. I have used both of these caustics frequently, and, whilst bearing testimony to their efficacy, I feel bound to state that I have never seen any evil resulting from such practice.

The subject of stricture attracted, fifteen or twenty years ago, even more than the usual attention bestowed upon it, from the circumstance of Mr. Syme having strongly urged division of the obstruction through an incision in the perineum. Whilst that gentleman has advocated the practice with his well-known zeal and enthusiasm, and published many cases illustrative of his views, others have questioned its propriety or supposed advantages. Unfortunately some have spoken and written on the subject who have been indifferently qualified to give an opinion, and others, without experience, have openly condemned the operation as uncalled for, hazardous, and useless to boot. A degree of acerimony has been displayed by most parties engaged in the
TREATMENT OF STRICTURES.

701

controversy (if it may be so styled) which is greatly to be regretted, especially as the subject is of extreme importance in all respects. Doubtless it will be more dispassionately examined in the course of time, and then the treatment of certain cases of stricture, by the so-called "perineal section," will stand or fall by its own merits. Meanwhile many of those who have ventured to give an opinion upon it have evidently confounded Mr. Syme's proposal with the operation for certain diseased states of the urethra and perineum, which has been more or less in general use for the last century, and is certainly as old as the time of Wiseman; and moreover have seemingly taken up the idea that he applies this as a general mode of treatment, whereas it is only intended for special cases, and differs in some important respects from the operation described by Wiseman, Hunter, Cooper, and most modern authorities.

The operation recommended by Mr. Syme is intended for cases of a less formidable kind, and of more frequent occurrence. Every surgeon of experience must have met with examples of stricture, with little or no indication of mischief otherwise in the perineum, where the bougie has been productive of mischief, or where probably the disease, having been temporarily improved, has speedily returned, and where again and again there have been the same treatment and results. It is chiefly in such cases that the division of the stricture has been recommended, and in advocating the operation Mr. Syme sets down as fundamental rules for its due performance certain doctrines totally at variance with those generally held by surgeons. An instrument must be passed through the stricture, otherwise the perineal section cannot be performed. Surgeons have heretofore considered this the commencement of certain success with the after use of the bougie. Mr. Syme makes it essential that an instrument, however small, should be passed through the stricture, to guide the knife and to insure that the canal is laid open, and not any false passage that may be near it. To those who ask what is to be done when an instrument cannot be introduced, Mr. Syme replies that there is no such thing as an impermeable stricture, and that it is only the surgeon's want of skill which prevents the proper introduction. Everyday experience shows that one surgeon will introduce an instrument where another has not succeeded, but there are few who maintain that they never fail in this proceeding, and it is certain that the most expert operators have failed to pass instruments where there has been positive proof at the time, by the dribbling of the water, that the canal has been in some degree permeable.

Fig. 428.

The operation, as done by Mr. Syme, consists in introducing a slender staff or director about the diameter here indicated (fig. 428);
then, whilst the patient is placed as if for lithotomy, an incision about
an inch and a half long is made in the raphe of the perineum, between
the anus and scrotum down to the stricture; next the point of the
blade is pushed into the groove of the director behind the stricture,
which is then divided in a direction towards the scrotum. This
being done, the staff is withdrawn and a catheter of full-sized di-
mensions is carried along the urethra into the bladder, and so the opera-
tion is finished. The instrument is retained for several days, at
which date the wound in the perineum is probably closed. Its use is
continued longer if required, and either it or a bougie must be in-
roduced from time to time during the first fortnight or three weeks,
when the patients usually pass water comfortably and in a full
stream.

One of the advantages which I anticipate from Mr. Syme's labours
will be an encouragement to resort to the perineal section in many
instances of stricture and urinary fistula with concomitant evils, which
have heretofore been treated by the questionable palliative of the
bougie, or perhaps hopelessly neglected until the circumstances have
become extreme. Comparatively little is now said regarding this
proceeding.

Mr. Syme's reports published in the Edinburgh Monthly Journal,
and in The Lancet, were most favourable, and I have myself re-
peatedly seen the best results follow, but, like all other cutting ope-
rations, it is not devoid of danger. Even deaths from it have been
recorded, and besides evils from hemorrhage, shock, and other an-
noyances, I can from my own observation positively state that it is not
always followed by the entire relief from after annoyance that some
have been led to expect; and whilst I think highly of the practice in
certain instances, I am of opinion that, like all others in surgery
wherein the knife is required, it is not free from hazards, over which
the surgeon has no control, and that it should not be practised indis-
criminately, nor without a due regard to all the attendant cir-
stances. But the limits of this volume will not permit me to dwell
much longer on this subject, and I must refer those who are specially
interested in it to the writings of Mr. Syme, and to a volume by Mr.
Lizars on Stricture of the Urethra, published by him in 1851, in
which particular reference is made to certain cases of perineal section.
If the surgical works of Desault, the lectures of Amussat, already re-
ferred to, and the more modern volumes relating to strictures of the
urethra by Leroy and Civiale, had been more familiarly known by the
profession in this country than they seem to be, there would possibly
have been less said and written on the use of the knife in such cases
than there actually has been. Among the various works on the
urethra and on strictures with which the press may be said to teem, I
have much pleasure in paying a passing tribute to the able lectures of
Mr. Hancock, delivered many years ago before the Medical Society of
London, and now published in a distinct volume, as also to the
valuable Essays of Sir Henry Thompson, 1854, and Mr. Henry Smith,
1837.
Besides the "perineal section" various other methods have been followed. Many years ago the late Mr. Stafford brought under notice a form of lancet-catheter, such as that here depicted (fig. 429). The point of the catheter is intended to be pushed against the stricture, and the lancet, marked by the dotted lines, which has been concealed in the tube, is intended to be thrust into the obstruction. The instrument may be straight, as here presented, or curved like a common catheter. French surgeons have displayed great ingenuity in these instruments for cutting stricture, and I may refer those who are particular in such subjects to the modern books above named. Some of these are intended to cut in the direction towards the bladder, and others as the instrument is being withdrawn—a practice highly extolled by Civiale. The term "scarification" is hardly known among English surgeons as applied to the treatment of stricture, but it is in common use with French authors. In modern times, since subcutaneous sections have become so common, it has been proposed to divide the stricturc of the urethra in this way, but the plan above referred to seems preferable. The lithotritist sometimes finds the orifice of the urethra narrow in comparison with the rest of the urethra, and therefore slits it open to permit the free use of his full-sized instruments. I have myself repeatedly, in treating slight strictures within an inch or two of the glans, introduced a narrow bistoury or a common director, and incised the contracted part to such an extent as to permit the ready introduction of a good-sized bougie or catheter. I have been so pleased with this plan that I have tried it deeper in the urethra than an ordinary bistoury could reach, and have used a simple contrivance, such as is here represented (fig. 430).
excellent effect. The director being passed, the knife is slid along and its cutting edge used at the seat of stricture. In some instances I have been content with a single incision at the lower part of the tube, in others I have notched or "scarified" the stricture all round, and immediately thereafter been enabled to introduce a bougie of considerable size. The blade and stalk are a little longer than the director, and the cutting point may be pushed forward if desired, although in the deep part of the urethra this plan is not to be recommended, and should be ventured on solely by one fully acquainted with the anatomy of the parts.

If I may venture on ticklish ground—for most writers on stricture seem to be particularly pugnacious—I am disposed to think that a great error has been committed by many authors on the subject, viz., maintaining that a special and favourite mode of practice is the best for all cases. If all strictures, all constitutions, and all circumstances of patients were exactly similar, such a mechanical view would perhaps be of great value to the unfortunate sufferers from this disease, but it is not often that two cases are met with exactly alike in all respects, and the judgment and skill of the thoughtful and experienced surgeon are required to select the proper course of treatment for each case, both at a particular time and under its varying phases.

Thirty years ago the practice of applying the nitrate of silver to the urethra, especially at the orifices of the seminal ducts, was, in accordance with the views of Lallemand, much in vogue. Whilst willingly giving my humble approbation to such treatment of irritable urethra and so-called spermatorrhœa, I cannot but express a fear that a loophole has been left for the assumption of certain methods of practice and affected skill by no means creditable to the profession. M. Lallemand's name was, however, a high authority, and here is (fig. 431) a representation of an instrument which he recommended

Fig. 431.

to be used for the purpose alluded to. It looks in most respects like a common catheter, but the external tube contains a long elastic wire which is attached to the point of the instrument, and immediately within which point there is a kind of cup, which can be projected by means of a wire beyond the tube, so that the caustic which fills the cup may be brought into contact with the part of the urethra required to be touched with the agent in question. The instrument is here, for the sake of the page, represented in two portions. In one the cup for holding the caustic is displayed as if it were projected in the urethra when in use; in the other, the handle of the instrument, as it may be
called, is shown, the upright screw being for the purpose of giving exact limit to the extent to which the point may be projected. The instrument may be either straight or curved as may be deemed requisite. When it is intended to touch the back part of the urethra, perhaps the curve here indicated is best.

The application of various astringent and caustic solutions may occasionally prove of much service in certain cases of chronic discharges from the male urethra, and instead of injecting them, as is the common custom, a simple modification of the instrument just referred to has been recommended for the purpose by Mr. Henry Smith. A bit of sponge, instead of the cup, is fixed on the stilet near the point, and the deep part of the urethra can thus be touched all round by any fluid which the surgeon may desire to use on the occasion. A similar instrument is depicted in the work of Leroy already referred to, which he uses for certain examinations of the urethra near the neck of the bladder.

For further information on most of the subjects above discussed, I beg to refer the reader to the publications of Mr. Syme and Mr. Lizars; and in a particular manner to the volumes recently published by Sir Henry Thompson and Mr. Henry Smith, which, taken conjointly, have left little room to add to our present stock of knowledge.

In concluding this chapter I deem it right to mention, that there are many diseased and abnormal conditions about the female perineum and parts of generation that I have not thought it requisite to refer to, as such subjects are usually treated by authors on obstetric surgery. Vesico-vaginal fistula, diseased states of the female urethra and bladder, prolapsus, ruptures of the perineum during childbirth, are all subjects with which the well-educated surgeon must be more or less familiar.

CHAPTER VII.

STONE IN THE BLADDER. TREATMENT. SOLUTION. LITHOTRTTY. LITHOTOMY.

The symptoms of stone in the bladder are usually very unequivocal: frequent calls to make water, sudden stoppage of the stream, pain, after evacuation, in the neck of the viscus and at the glans penis, irritation in the region of the bladder, in the perineum, anus, and rectum, occasional discharge of mucus, blood, lymph, or pus, all afford the strongest presumptive evidence as to the presence of a calculus; yet most or all of these may be more or less conspicuous and none be present, while in other instances the stone may never have induced symptoms such as to excite suspicion. The only certain test of this disease is afforded by the sound—an instrument which in most respects
resembles the ordinary steel bougie, and which may be used in the following manner:—The patient being laid as in the proceeding for catheterism, the sound must be introduced in much the same manner, and when it has entered the bladder its point must be gently moved about in all directions until it strikes the concretion, when the sensation in the hand of the surgeon will be such, that he can scarcely err, and in addition, in most instances, the sound of the concussion is sufficiently distinct to be heard even by those in the immediate vicinity. If the stone is not touched at once, a change in the patient's attitude may alter its position; thus, if he turns slightly to one side or the other, raises the pelvis above the level of the shoulders, or stands erect, the search may be more successful. In some instances, a common catheter will be as efficient as any other instrument; but when there is doubt as to the metal having touched a stone or merely a hard surface within the bladder, the solid steel should be preferred. An ingenious device has been recommended by Mr. Brooke, of the Westminster Hospital, of placing a circular plate of wood upon the shank of the instrument near its handle, to act as a kind of sounding board. Where stone is palpable this makes it more so, but I should be sorry to trust to this alone, before operating on a patient for this disease. A shape like that of the common bougie or catheter will generally suffice for touching the stone, but it has become a prevailing custom to use a sound similar in shape, near the point, to that here exhibited (fig. 432), under the supposition that the short part beyond the curve

![Fig. 432.](image)

can be more readily moved about or turned down behind the prostate gland, so that the interior of the bladder may thus be more thoroughly examined. We are indebted to Baron Heurteloup for this shape of instrument, and I consider it so superior to all others, for ordinary purposes, that I invariably use it. In the figure, it will be noticed that the point of the instrument is thicker than the shank. This is a device of my own—so I suppose—and it permits more free motion in the urethra, while the thick end of the sound is moved within the bladder. With this shape, or with a large curve, it will sometimes be of advantage to raise the lower part of the bladder by introducing the forefinger into the rectum. In one example the stone can be touched most readily when the bladder is moderately distended with urine; in another, when it is almost empty: on one occasion, in the same individual the object may be most palpable, at another time, the utmost tact cannot detect it—and the latter will be observed, too, in instances where there is afterwards every proof that the stone has not in the interval passed into any pouch connected with the bladder: indeed, this condition is exceedingly rare—I mean that of a large pouch sufficient to conceal a calculus of ordinary dimensions. On all
Dissolving Stones.

occasions a small stone, as might be anticipated, is more difficult to detect than a large one, and in general, when one of moderate diameter (eight or twelve lines) is present, it is felt almost as soon as the instrument enters the bladder; for although a calculus may for a time lodge in any part of the organ, its most frequent seat is so immediately upon the orifice of the urethra, that it is often struck ere the curve of the sound has passed the prostate. It need scarcely be added, that all the movements with the sound must be made in the gentlest manner possible; on one occasion a slight rotatory motion with the hand will suffice; on another, the whole instrument must be carried inwards so as to tap the stone; and again, it may probably be necessary to draw it backwards in such a manner as to cause the concavity between the curve and point to touch the neck of the bladder on all sides.

Although it has been recommended that the sound should be introduced as for catheterism, it will be found inconvenient to use the right hand when the outer end of the instrument is between the patient's thighs: the left may therefore be used at this time; but as few possess the same delicacy of touch with the latter organ, the surgeon may, after having reached the bladder, place himself between the patient's thighs or stand upon his right side. For my own part, I generally introduce the sound with my left hand, while standing by the patient's right side, and then, when any minute search is required, manipulate with the instrument in my right hand.

In the event of stone being detected, the treatment may next be taken into consideration. Supposing that all those internal, or, as they may be called, constitutional means, which a knowledge of the practice of medicine will enable the surgeon to exhibit, have been tried and found of no avail (which in all probability will be the result), there are various mechanical proceedings which he may resort to, and which demand especial notice in such a work as this. The proposal to dissolve stone in the bladder by passing medicated fluids into that viscus is of old date. Towards the beginning of the last century the ingenious Dr. Hales used to show the possibility of passing a stream through the cavity by means of a double-tube catheter. His experiments were, however, performed on some of the lower animals, but he believed in the possibility of thus effecting the cure of stone on the human subject by solutions of the carbonate of soda. Since then, to the present day, little progress has been made in this mode of treatment; for although, from time to time the practice seems to have been successfully tried (as evinced by the cases occurring to Dr. Rutherford, Sir Benjamin Brodie, Drs. Kitter, Jurine, Petit, and others), it has attracted a small share of attention from the practical surgeon. Various solvents have been used on these occasions, from simple water to nitric acid—the latter being so weakened as not to injure the mucous lining of the bladder. Hales was aware of the power of a solution of carbonate or subcarbonate of soda over certain kinds of calculi, and the efficacy of Vichy water, whether as an internal or as a local remedy, depends, in a great measure, on the bicarbonate of soda which it holds in
solution. Dr. Rutherford used lime water; Dr. Ritter, caustic potash; Sir Benjamin Brodie, nitric acid—all, of course, in a diluted state. Dr. Hoskins, of Guernsey, supposed that he had discovered an effectual and safe solvent for phosphatic calculi in the saccharate of lead, but the results of trials with it have not, in so far as I know, served to confirm this high character. Gruithuisen, although seemingly impressed with the virtues of simple water, entertained the idea that the strength of its current might have no inconsiderable influence, and so (perhaps with more mechanical ingenuity than surgical discretion) proposed to carry a stream through his double catheter by a tube communicating with a reservoir on the top of a two-story house! Professor Jurin, of Geneva, was of opinion that injections of water had caused such a change on a large calculus in one of his female patients, that it broke down into many fragments.

This method of treating stone, if it be of any value, might now be more favourably resorted to than in former years; for, instead of the periphery alone being attacked, the object might be previously broken into fragments, whereby a vast extent of additional surface would be exposed to the dissolving and disintegrating influence of the menstruum.

The fluid may be carried into the bladder by means of a catheter and syringe,—or a caoutchouc bag with a proper nozzle may answer. A flexible caoutchouc catheter may be used on these occasions; silver, however, is generally preferred; and when Sir Benjamin Brodie injected nitric acid, the catheter was made of gold. A double tube—so constructed as to resemble externally a common catheter—had better be used, whereby, if it is desired, a continued stream may be kept up. For this purpose Hales, Gruithuisen and others, used the
instrument like a syphon,—a dish with a communicating tube being kept above, another below. A Read's syringe may be applied for the purpose, and such an apparatus I had constructed many years ago. In the middle figure of this cut (fig. 433) is a representation of a catheter, and the dotted line, as also the star, marks the division of the tube into two. At a the nozzle a of the syringe is received. Fluid passing along flows into the bladder through the eye marked by one arrow, and into the other eye similarly marked, from whence it finds its way out at d. In the event of the eye or tubes being obstructed by fragments of stone or other material they can readily be cleared by the metal stilet marked c c. The point of this useful part of the apparatus nearly fills each tube, and to permit its being pushed along at the curve of the tube, the steel is thin and elastic, so that it bends readily as represented by the dotted line. This rod can be introduced at a, or at the orifice which is represented as filled by a plug marked b. Mr. Weiss constructed some instruments in the form of those which I have used, and had them gilt so that they will resist the action of any ordinary solvent.

Instead of a single stone there may be several, or there may be numerous small concretions, varying in size from a mustard-seed to a garden pea. Although in such cases there may often be every reason to suppose that some, if not all, of the little bodies are originally formed in the kidneys, and drop down the ureters into the bladder, the practice above alluded to may be equally applicable. Here it is evident that local measures alone will not suffice; but even while constitutional remedies are being exhibited, some may advantageously be tried. Besides attempting to dissolve these objects, or possibly without trying such a plan at all, some method more strictly mechanical may be resorted to: the urethra may be dilated to the fullest possible extent by means of bougies or otherwise, and thus there will be a greater probability of the gravel passing away in the natural stream; the double current apparatus above described may be used with effect in some of these cases, or a full-sized silver catheter, provided with one or two large eyes, may be introduced, and, the cavity being distended with fluid, the small stones may pass along the tube, or possibly in withdrawing it slowly, while the fluid is still in the viscera, a few may follow its point. Such plans have been known to succeed, as evinced in the practice of Ledran, Boyer, Sir Benjamin Brodie, and the late Mr. George Bell, of Edinburgh,—who was thus fortunate in ridding a patient of one hundred and fifty concretions,—and in other cases the calculi have been seized with instruments made for the purpose, and extracted at once. The instance where Sir Astley Cooper was so successful as to cure his patient by extracting upwards of eighty small stones in this way, is the most celebrated of the kind. Mr. Weiss, who constructed the original instrument used for this case, has made it in some respects more perfect. This drawing (fig. 454) exhibits its shape and appearance: at the point it consists of two blades hollowed within, which can be caused to open by means of a stilet, connected with a kind of trigger near the handle. When in the
bladder the blades are opened, and allowed to shut again, which they
do by their own elasticity, provided the trigger is set free; and,
more perhaps by chance than by dexterity or precision of move-

Fig. 434.

ment, one, two, or more of the concretions are probably caught within
the hollow chops. By a repetition of such proceedings from day to
day, as circumstances permit, the offending bodies may thus be
removed. The method, however, is of older date than Sir Astley's
operation, although the instruments do not seem to have been so
perfect. Sir William Blizzard was occasionally in the habit of resort-
ing to it, and the proposal is at least two centuries old. But cases
where such practice may be deemed advisable, or may actually prove
of service, are truly of rare occurrence, and in by far the greater
number of instances of stone, some more effectual means must be
resorted to. In the present day the scoops used after lithotripsy,
referred to a few pages further on, for the purpose of removing small
fragments, would probably be preferred to the instrument above
delineated.

It is not compatible either with the limits or with the arrangement
of this volume, that I should enter upon the particular history and
progress of the subject of lithotripsy, which now occupies so large a
share of surgical literature and practice. The celebrated cases of
General Martin and the monk of Citeaux seem invariably to be put
at the top of the list of all lithotritic proceedings. The former re-
lieved himself by frittering the stone into sand by means of a steel
bougie made rough like a file on its convexity: the latter, by means
of a kind of chisel introduced through a canula, and made to act on
the stone by percussion with a hammer. The General's bladder is
said, however, to have held a stone within it when he died, and the
relief which he experienced may probably, after all, be attributed to
some of those accidental alterations, as to position of the stone and
otherwise, which are occasionally met with in practice where no
mechanical means have been adopted, and which are well ascertained
to have occurred in some instances during the exhibition of the
nostrum of Madame Stephens. Although Gruithuisen, of Munich,
proposed, in 1813, to seize and then perforate a stone in the bladder
by the process of drilling, thereby to permit of the more advantageous
contact of solvents, and though Dr. James Arnott, in 1821, proposed
applying a small circular saw, introduced through a canula, to rasp
off a portion of the concretion; though Elderton, in 1819, first pro-
posed a curved lithotritic instrument, and though Anussat, Leroy,
and Civiale were busily engaged simultaneously on the project of
destroying stone in the bladder by mechanical means, the first operation on the living subject at all resembling the modern proceedings was not performed till 1824, when the last-named gentleman succeeded in freeing a patient of his complaint by the application of instruments on only two different occasions,—sittings, as they have been technically named. Since this date the operation has been very frequently performed, both by those who have devoted their sole attention to the subject,—among the most celebrated of whom may be named Civiale himself, Heurteloup, and Costello,—and by the regular surgeons of the day. The names of Amussat, Leroy, and Ségalas occupy distinguished positions in the interesting history, and it were needless to mention the various surgeons of our own country who have resorted to this operation, as there are now few in large practice who have not had many opportunities of becoming familiar with it.

Like many other novelties, lithotritv has undoubtedly been too much vaunted by its professed advocates and performers; but it is equally clear that in many instances it forms an admirable substitute for lithotomy. Notwithstanding the reputed success of Civiale, it seems to me that in the present stage of its history we have not sufficiently authentic data by which to determine the comparative safety of lithotritv to that of lithotomy; but regarding its applicability, and even superiority in many instances, there need be no doubt. Years must yet elapse, and the operation must be tested in our public hospitals by the same class of surgeons as those on whose proceedings the statistics of lithotomy have been founded, before an unbiassed professional judgment can be given on the subject. In my own practice I now find that I perform lithotritv both more frequently and more successfully than in former years; but generally the cases occur in private practice. Perhaps the reason of this is, that among those who do not seek hospital aid, it is more generally known that if the surgeon is applied to at an early date there is a better chance of the case proving suitable for this proceeding.

There are certain circumstances adverse to the success of lithotritv, which should always be inquired into, ere it is determined to resort to this operation. The diameter of the urethra before the age of puberty is most unfavourable, both on account of the smallness of the instruments which must of necessity be used, as also that the fragments cannot pass away in large portions. Besides, in early years the urethra and bladder are more irritable and less callous to the contact of the needful apparatus. At any period of life a small urethra is objectionable on the above grounds, whether there be stricture or a natural want of development. Any obstruction to the free passage of instruments or of urine must be a great hindrance; and in advanced years the natural enlargement of the prostate, and what may be termed the diseased enlargement, present impediments which the utmost skill may not be able to surmount. Should the bladder be sacculated—a condition which can scarcely be ascertained on the living subject—the chances of success will be further diminished; for, supposing the stone to be broken into various frag-
ments, the probability of some of these lodging in such pouches, must always render the results of the proceeding uncertain. But from my own experience I should say, that the most formidable objection to lithotripsy is the apparent irritability of the urinary organs: if the patient does more than wince while being sounded; if the application of the steel to the urethra seems to occasion pain—I mean more than that sensation which patients usually have on such occasions,—if the mucous surface of the bladder is so tender as to cause the contact of the instrument to be borne with difficulty, and if the muscular fibres are excited to such violent contraction as to occasion the escape of the urine along the side of the instrument, or to excite an irresistible desire to micturate, then assuredly the circumstances are peculiarly unfavourable to the proceeding. A stricture may be cured; the natural calibre of the urethra may be increased by dilatation; even in certain cases the objectionable state of the prostate may be in some measure overcome by means of large catheters, scoops, and proper position whilst voiding urine; but the irritability—excitability I may call it—and tendency to inflammation, which are almost certain accom- paniments, cannot so readily be coped with. It is well known that in some instances the organs become more and more callous after the application of instruments; but it is equally clear that the conditions above referred to often rather increase than otherwise, after the first, second, or third sitting; and, in addition, that in many cases, these objectionable features, although not conspicuous before the operation, have become so developed as to retard the whole proceedings, making each succeeding attempt more painful than the preceding one, so that the cure may be both painful and protracted.

All these observations regarding temporary suffering from the application of instruments are completely set aside by chloroform; and where most of the features above referred to have been present in a marked degree during the ordinary process of sounding without chloroform, I have, under the use of this agent, been enabled to effect the complete breaking up of the stone in a single operation, without the patient's consciousness, and happily without subsequent evil. In the early days of anaesthesia, it was doubted by many whether it would be wise to make the patient insensible to pain during this operation; in fact it was then said that pain was the only guide to the surgeon that he was doing wrong. This view is still maintained by some; but for my own part, I am of opinion that there is not any department in practical surgery in which anaesthesia has been of more service than in this, and wherever there is great irritability, I almost invariably use it on such occasions, with the best possible effect. Almost the only objection I have to chloroform on those occasions is, that patients who are unruly under its influence are apt to struggle, and so obstruct the surgeon in that nice sense of touch which is so valuable in dealing with fragments.

It must be admitted, however, that the effects are very different in the majority of cases in which lithotripsy is properly applicable, for when the circumstances are favourable, viz., when there is a large and
callous urethra, a capacious and apathetic bladder (if I may so call it) —possessing good muscular power, a healthy prostate, and a small or moderately-sized stone, the operation may be done once, twice, or as often as may be required, with as little annoyance to the patient as if he were only undergoing the treatment for stricture.

Crushing the stone into fragments is the method now in general use, having almost entirely superseded the percussing force of Heurteloup, and also the process of drilling by means of a straight instrument, which was in early days used by Civiale, but which, we learn from Mr. Edwin Lee, in his Dissertation on the subject, for which he was awarded the Jacksonian Prize for 1838, was scarcely even then employed by that distinguished lithotritist. The curved instrument originally devised by Mr. Weiss, in 1823, formed the type of those which have since been so much improved—it may be said perfected—by himself and M. Charrière; and among those who have particularly distinguished themselves by their ingenuity in the construction of lithotritic instruments, Mr. L'Estrange, of Dublin, deserves especial notice. The lithotrite of the present day consists of a male and female blade, which, while they are so adapted to each other as to resemble a common short-curve sound, can, by a sliding motion, be so opened at the extremity within the bladder as to leave a space of sufficient size to enclose the stone, when they may again be pushed towards each other, and with such a force, as to divide the object into two or more fragments, which can each be treated in a mode similar to that by which the original stone has been broken down. This force is generally, as Mr. Weiss originally proposed it should be, applied by means of a screw; Heurteloup, however, who first used the instrument, preferred a hammer wherewith to close the blades; but the screw has been again adopted, and it is scarcely possible to refer to any useful piece of mechanism for surgical purposes more perfect than the instruments now constructed by Weiss of the Strand, and Matthews of Portugal-street.

This figure (435) shows one form of screw on the plan referred to.

The instrument is adapted for crushing large concretions, and no stone of ordinary dimensions or density could withstand its power. Figure 436 represents another of Mr. Weiss's instruments, of simpler construction and lighter make. This is generally used to deal with fragments, and the blades at the points are so shaped, that while they are strong enough to obey the crushing force, they are hollowed out to retain some of the stone, and thus permit its removal from the
bladder. For this latter object the instrument is a semicircle or shell on its convexity, near the point, but that used for crushing the

Fig. 436.

stone itself, or the large fragments, is generally open on the back, so that purposely no detritus may be collected. These features are more clearly delineated in the two figures here represented (figs. 437 and 438), the first showing the large fissure or gap to permit the fragments to fall readily away, the other the cup to collect them, so that they may be removed between the blades—entire or squeezed into a mass—as may be.

In 1834 I described, in The Lancet and in the Edinburgh Medical and Surgical Journal, a modification by means of a rack and pinion, which I was induced to prefer after having witnessed some operations with the apparatus of Heurteloup. The necessity for a vice in which to fix the instrument, the complicated, though ingenious table, and the various processes of fixing and unfixing the different screws and pins, all seemed to me to be unnecessary. The vice, capable of being fixed at any proper height on the margin of the table, was at first deemed a most valuable means of preventing the percussion from acting injuriously upon the urethra or bladder—it certainly was admirably adapted for that purpose; but it was entirely overlooked that, while the lithotrite was in the viscous and thus fixed, there was nothing which could prevent the patient so moving and writhing his body as to bring the bladder against the instrument, and thus unconsciously inflict greater injury than might have been occasioned without the vice. I have nowhere seen this circumstance so clearly pointed out as in Mr. Lee's Essay, already referred to. A hand-vice has been substituted by some; but it may well be doubted if there be further use for the hammer, as the screw above referred to, or the apparatus delineated in figure 439, affords as much destructive force as the limited size and strength of the instrument will bear.

Of late years I have in some respects simplified my own contrivance, and generally give it the preference to the screw force. It is such as may be understood by drawing 430, or that numbered 440, which exhibits an instrument scarcely heavier than a common sound or bougie, and may be used in the following manner:—The
patient being laid on a bed, or a couch, with the shoulders and knees slightly elevated, and the pelvis slightly raised on a pillow, the surgeon,

*Fig. 439.*

standing on either side, should introduce the instrument, with the blades closed and smeared with oil or lard, in a slow, steady, gentle manner, so as to cause the smallest possible excitement: next, when

*Fig. 440.*

the curve is fairly within the cavity, he should cautiously feel for the stone, as in the process of sounding already described; having touched it, he should open the blades by drawing the inner one towards him and pushing the outer a little onwards, until he supposes the gap sufficient to include the calculus, when he should turn their points and dip the whole end of the instrument in the supposed direction of the stone, push the blades towards each other, and thus grasp the object: this being done, he should move the instrument slightly by way of making sure that part of the muciuous membrane is not included, and being satisfied on this score, he should apply the handle (*fig. 441*), and by turning it in the manner indicated by the accompanying drawing (*fig. 442*), should force the inner blade onwards, either by a continued turn of the hand, or by sudden and short jerks, so as to imitate slight percussions, until the object is shattered, when he may repeat the proceedings on one or more of the fragments, according to circum-

*Fig. 441.*

...
stances. In recent years I have found it most suitable to stand on the patient's right side, to introduce the instrument with the left hand, and then, as the handle lies between the patient's thighs, to use the right hand chiefly whilst opening and shutting the blades. With the fingers and thumb of my right hand I can readily move the blades, and when the crushing force is being applied, I hold the instrument as here depicted in figure 443. The whole proceeding

Fig. 443.

is, perhaps, more efficiently completed in this way than in the manner represented in the cut 442.

Mr. Liston used the first lithotrite which I had constructed, and declared it (Lancet, 15th of February, 1834) "safer and more efficient than any he had yet seen" for crushing the stone; and the figure (439) on the preceding page has been represented by Civiale, in his work on lithotrity, as the "most simple" with which he was acquainted. Mr. Weiss has made some slight changes in this, having placed the rack below again, where I originally had it, with a little modification of the handle and the place for its reception. The French makers have kept the rack above, with the contrivance about the handle here represented (fig. 444) from one of Charrière's instruments. By an ingenious

Fig. 444.

Parisian modification the rack consists in a series of circles, and the part for the reception of the pinion or handle is made to revolve in such a way that the handle can be applied with ease in whatever position the instrument may lie. There is, however, more ingenuity than utility in this arrangement, and I still give preference to the
LITHOTRITY.

instrument represented in figure 439. Perhaps, besides simplicity, one of the chief recommendations of the rack over the screw is, that the outer blades can be worked upon the inner—a movement which I often find of advantage—and the crushing force can be applied in a much more rapid manner than with the screw. With the latter, in order to let the inner blade work, the screw must be well back in the handle, and when the stone is caught a number of turns are required ere pressure can be applied; also when the stone is broken, or should the fragment slip, the screw must be undone and turned up again ere the force can be renewed. With the means above recommended, however, the pressure can be applied directly, and taken off with equal rapidity when required, so that the blades can be moved immediately and brought into action with much greater facility than when the screw apparatus is used.

These latter objections have, however, been entirely done away by a new method of applying the screw. This figure (445) represents

Fig. 445.

the handle of the instrument. The thickest part is a slide, which on being slipped backwards or forwards relaxes or fixes the grasp upon the screw. When not fixed the outer and inner blades can be moved separately, at will, in opening and shutting the blades, and when fixed the screw force can be applied by turning the wheel or circle at the extreme end. This mechanism is a slight modification of that preferred to any other by Sir Henry Thompson, whose dexterity in using it I have repeatedly observed and admired.

Perhaps if the stone be broken, and each large fragment treated in the same way without withdrawing the instrument, one operation may suffice; but more frequently repetitions must be resorted to at intervals of two days, or more, according to the original magnitude of the stone and condition of the bladder above referred to. Previous to the performance of each operation, the patient should be desired to retain his water for a couple of hours or more, or else some tepid fluid must be thrown in immediately before. When the cavity is tolerably distended, the instrument moves about with more facility and less pain to the patient,—besides, the stone is more isolated, as it were, and the blades can be placed on each side of it with less risk to the mucous membran. Usually towards the end of each proceeding, the bladder becomes comparatively empty, from the escape of urine through the chinks and alongside of the instrument, and if such be the case, as the blades are more likely to inflict injury, they should be closed and withdrawn. It will seldom happen that there is not some slight effusion of blood, the urine being generally tinged red for some time after, and clots occasionally pass away, either by themselves, or mingled
with sand and small fragments. For the purpose of clearing the bladder as rapidly as possible, Heurteloup used an instrument of steel resembling a common catheter, through which, when introduced after the operation of breaking the stone, he injected tepid water until it was forcibly expelled, when clots, sand, and small fragments at the same time occasionally escaped through the eyes, which were purposely made very open. In case of any large fragment sticking in these apertures, a most ingenious stilet, constructed towards the point like a watch-chain, was introduced so as to cut them off, and allow the instrument to be withdrawn without injury to the urethra from any portion projecting through one or other of these openings. The double-current catheter, with Read’s syringe, already referred to (p. 708), I have used with similar objects.

The subsequent treatment must be conducted on ordinary surgical principles. When the stone has been divided, a smaller instrument than that which has originally been used will suffice for the fragments, which are on some occasions so very friable that the mere squeezing of the blades together with the palm and fingers will suffice to crush them. The teeth may vary considerably in shape from those represented in fig. 439: the two blades may be so made that the one encloses the other, as in fig. 439, or they may be opposed, as is represented in this cut (fig. 446). The instrument generally in use is open on the back between the turn and the point, so that the fragments cannot clog up the blades and prevent them from being readily shut; but sometimes a kind of scoop is used—one blade having a large excavation, the other forming a sort of lid for it. Some of these are so constructed as to suit for catheters at the same time. In one instance such a curve as that represented in the sketches referred to may be found to answer best, in another the angle may be more or less oblique. In some instruments the point beyond the curve is longer, in others shorter, as here exhibited (fig. 447): but the minute details of these matters would carry me far beyond my present limits.

Occasionally both patient and surgeon experience more annoyance from a fragment lodging in the urethra than from any other circumstance, and much ingenuity and manipulative skill may be necessary to expedite its passage. Various instruments have been constructed to enable the surgeon to extract these objects. One of this figure (448) may sometimes answer: the two blades are intended to grasp the fragment, and the screw or file in the centre is designed to fritter it down. In one instance a bent piece of wire will suit, in another the scoop end of a common director, or such a scoop as is represented at p. 521, made an inch or two longer to reach, if needful, down the urethra; and again, a long slender forceps, similar in construction to those used for extracting polypi from the nostrils (p. 490), will serve
the object in view, particularly if the fragment is not far back in the passage, or the construction may be such that on opening the blades

Fig. 448.

Fig. 449.

the jaws may be as represented here (fig. 449), between which the stone may be grasped and held firm during extraction. The instrument I have found most generally useful in the predicament last alluded to, is one like this (fig. 450), a part, in fact, of the original apparatus of Civiale, being a diminished size of his three-bladed straight instrument for drilling. But I need not dwell on such topics, nor, after all that has been previously stated in this volume, need I give special notice to matters which the ordinary principles of practice should dictate,—as regards the necessity of using every instrument with the most gentle and delicate movements,—the value of opiates, especially when exhibited by the rectum,—the advantages of diluents, hip-baths, and generally, all such means as shall allay pain, promote the passage of fragments, avert or subdue inflammatory action, and give tone to the urinary apparatus.

Although lithotrity has been successfully performed on boys, it may well be doubted if such a proceeding should generally be attempted upon them; for it would be difficult to name any single operation of magnitude which has been more successful on young subjects than lithotomy. Out of one hundred and five cases operated on by the latter method in the Norwich Hospital—the patients being under ten years of age—only three died, thus giving an average of one in thirty-five; and although other tables do not show altogether such favourable results, there are good reasons for supposing, that the average deaths in young persons who are subjected to lithotomy is little more than one in twenty-eight or thirty. At one time in my own practice I could count forty-three cases of successful lithotomy on patients under puberty with the exception of only one death. Until it can be shown, then, that lithotrity surpasses this success, and is in almost every other respect to be preferred, it is only a fair conclusion to draw at the present time, that lithotomy is decidedly preferable in such subjects; and when, moreover, the comparative frequency of the disease in children is taken into account, it will at once appear that a large proportion of all cases of stone must yet be set aside for the lithotomist. Above the age of puberty, however, the average success alters very mate-
rial, and, as already stated, the propriety of resorting to lithotritry ought to have due consideration.

The circumstances which are unfavourable for lithotritry can be considered as giving only a negative advantage to lithotomy: if the magnitude of a stone precludes the selection of the former, it renders the latter a dangerous alternative; but of two evils the surgeon's judgment has to determine which can be deemed the least; it seems certain that the latter method must still, in many examples, be the only means of attempting a cure by operation.

Stone in the bladder is comparatively rare in the female, yet the surgeon is occasionally required in such instances, and he has a choice of means of extracting: he may dilate, lithotritize, or cut, as may seem most desirable.

Dilatation of the female urethra may be carried to a far greater extent than in the male, and very large stones, weighing several ounces, have been satisfactorily removed in this way. The process may be effected by means of sponge-tent, bougies, or metal dilators made for the purpose. For a small stone, the sponge or bougie may answer; but if it be large, I should prefer the dilator. The best, I think, is that which consists of two or three blades accurately fitted to each other, of a size when together that they scarcely exceed the bulk of a common sound, and capable of being separated by means of a screw. The accompanying figure (451) represents one of Weiss's two-bladed instruments for the purpose above referred to. The black lines show the instrument closed, the dotted lines indicate the position of the blades when they are thrown asunder by the screw attached to the handle. The dilator of the Arnotts, or expansion by means of water, recommended by Dr. Willis for Lithectasy, might be very useful for the proceeding in question. By any such apparatus the female urethra may be dilated to the requisite extent in the course of a few minutes, hours, or days, as may be deemed best. If the process be effected rapidly there is perhaps less chance of the urethra regaining its tone than when it is done more slowly, and it is therefore usually deemed best to let some hours at least elapse during the use of the dilator. When the passage is sufficiently large to admit, if need be, the forefinger, the surgeon can then judge of the propriety of using the forceps or scoop, as in lithotomy in the male.

Lithotritry may with great advantage be resorted to in many cases
in the female, with or even without the preliminary of dilatation, as from the nature of the passage, and size and force of the stream of fluid from the bladder, there will be greater chance of rapid success than in the male subject: indeed, with the modern advantages of chloroform, and a more perfect manipulation with the lithotritic apparatus, I should now rarely think of any other operation for stone on the female than lithotritry. These remarks apply to children as well as the adult. I have, on several occasions, performed lithotritry on female children about three years of age, and been both astonished and pleased at the results. I have had instruments made suitable to the size of the urethra, and found them sufficiently powerful to break such a stone as might be expected at this age. Under chloroform the operation has been performed without the consciousness of the surgeon's presence, and if a second application of the lithotrite has been needed, the proceeding has been equally simple. In these cases I have found a scoop, like that represented at page 521, has enabled me to remove all the fragments of stones of considerable dimensions at a single or a second attempt, and thus the little sufferer has been relieved of her malady without having been aware that anything had been done. Sir Henry Thompson has related an interesting case of the kind here alluded to in the second volume of The Lancet for 1854. In that case he previously dilated the urethra, but in my opinion there is little need in such instances for such a preliminary.

Perhaps in consequence of the great size of the stone, or other circumstances, it may be thought best to perform a cutting operation, and the bladder may be opened above or below the pubes at the choice of the surgeon. The high operation will rarely, if ever, be required; and a variety of proceedings below the pubes have been recommended, of which it is difficult to say which is best—a difficulty arising, in my opinion, from want of experience or statistical data. Lisfranc recommended that the neck of the bladder should be opened through a semicircular incision between the arch of the pubes and the urethra,—a proceeding which, so far as I know, has never been done in this country; it has by some been thought advisable to open the bladder from the vagina,—a step which has obtained as little favour as that just alluded to, and both of them have been devised for the purpose of leaving the urethra untouched. I once removed a stone from a young female by opening the bladder through the vagina, with the view of stitching the wound, to obtain union by the first intention. Both operation and stitching were difficult. Union did not take place, and months afterwards the urine flowed by the wound. The parts were too small for such a proceeding. Most of the cutting operations have involved the urethra: the most common proceeding has been by laying open this tube and the neck of the bladder on the left side, and at the same time making the requisite incision downwards and outwards parallel with the ramus of the pubes, to permit the extraction of the stone between this process of bone and the vagina. Some have proposed to open the urethra and neck of the bladder on both sides,
and others that a single incision should be made upwards from the urethra to the angle of the pubes. Of these methods I prefer the incision on the left side as above described; but as I believe that the operation may be successfully accomplished without cutting the neck of the bladder at all, I should in general proceed in the following manner:—The patient being secured in the same manner as for lithotomy in the male, a straight staff should be introduced into the bladder, having the groove downwards and towards the left side; a straight probe-pointed bistoury should then be passed along the groove until it has nearly reached the bladder, when it should be withdrawn, and at the same time applied to the soft tissues, so as to open the anterior half or two-thirds of the urethra, and cut downwards and outwards to the extent of half an inch or a little more; should the stone be deemed large, a slight notch may be made on the right side of the urethra somewhat similar to the first,—and this may be done with or without the aid of the staff, as the operator may deem best; the staff being withdrawn, the forefinger of the left hand having been previously dipped in oil, should be slowly passed along the wound and urethra into the bladder, and used with a gentle force to dilate where the knife has not touched; the finger being gradually introduced should be used to bring the stone towards the neck of the bladder, and should then be withdrawn to make room for the forceps: these should now be carried through the opening, and the stone, being seized, should be extracted by movements similar to those recommended on the male. The outer end of the female urethra, I believe to be the least dilatable of any part of the tube, and hence my reason for recommending its division; but the neck of the bladder is easily dilated, and unless very roughly used, will, as I imagine, speedily regain its tone and use. By a proceeding similar to that just described, I have extracted a stone from an adult female nearly three inches in circumference, and the patient has had the power of retaining her urine immediately after. An operation analogous to this was strongly recommended by Sir Philip Crampton, in his able and interesting paper on lithotomy, in The Dublin Quarterly Journal, for Feb. 1847, and other instances occurring in my own practice at King's College Hospital—one of which is described in The Laneet, Sept. 12th, 1846, enable me to recommend the operation strongly. All the operations on the female for this disease which have implicated the urethra and neck of the bladder, whether by dilatation or cutting, have been occasionally followed by inability to retain the urine, and afterwards the patients have been in a very miserable condition.

I propose here, in accordance with the arrangements in other parts of this work, to limit my notice of lithotomy in the male chiefly to an exposition of the practice which I myself should follow, and of which I can speak from personal experience. Cutting on the grieve is not practised by any surgeon of the present day; the operation with the apparatus major is equally obsolete; the high operation is never performed in this country, except in cases where other modes are not deemed eligible; the recto-vesical method has few if any advocates; the
bilateral proceeding is but rarely pursued; the cutting gorget has been nearly, if not entirely, laid aside, and the lateral operation, as practised by Jaques in his latter years, by Rau and by Cheselden, seems, with few exceptions, to be that in most common use among the modern surgeons of this country. The whole proceedings, as practised by some in the present day, so nearly resemble those of the last-named most distinguished of all British lithotomists, that the custom prevails more than ever of calling the operation Cheselden's. With some slight modifications, the following is a description of the proceeding, and such as I should recommend:—Every care being taken, as in all other operations, whether capital or not, that the patient is in as favourable condition as circumstances will permit, the perineum should be shaved, a clyster of warm water should be administered about an hour before, and after its action the urine should if possible be retained until the operation. Before the appointed time the surgeon, particularly in the early part of his practice, should have ascertained that there is a stout table in the apartment, and also a chair, each of a proper height in proportion to his own idea and size; and here too, as in all operations of magnitude, he should see that all his apparatus is in perfect order, as has been especially recommended in one of the early chapters in this volume. Everything being prepared, and chloroform having been administered, the first step is to introduce the staff, which should be as large as the urethra will admit with ease, and of such a shape as that delineated (fig. 452), having

Fig. 452.

the groove presenting a little to the left side of the urethra. This being slowly and cautiously done, as with the catheter, in the manner already described, the instrument should if possible be made to strike the stone, and should then be given in charge of an assistant. Next, the patient should be secured thus:—A piece of broad worsted tape about three yards long should be doubled, and formed into a loop in this fashion (fig. 453), which should be fastened on one of the patient's wrists; and then the hand being placed on the outer margin of the foot, the two ends should be so twisted round both hand and foot as to bind them firmly together. A similar manœuvre should be executed at the same time on the other side, and thus he will be securely bound, hand and foot, although two assistants will be required, one at each knee, to hold the thighs properly apart, and
others will also be required to keep him steady. In former days, before the introduction of anaesthesia, this was one of the most disagreeable parts of lithotomy, for both patient and surgeon, and often

In former days, before the introduction of anaesthesia, this was one of the most disagreeable parts of lithotomy, for both patient and surgeon, and often

I have seen the bandages most inadequately applied by the operator and his assistants. In later years I have found that a leather strap round the wrist and foot on each side, attached by hook and ring as here (fig. 454) represented (for the left side) has answered the purpose of the old-fashioned bandage admirably, and I am much astonished that this simple plan had not been thought of long ago in the progress of this remarkable operation. These straps I consider a great improvement upon the gaiter and wrist-band, which I have occasionally used, and seen used, as something better than the old bandages.

The breech should now be brought to the margin of the table, when the assistant who has charge of the staff, should be desired to hold that instrument in his left hand, nearly perpendicular, with the concavity of the curve touching the upper part of the triangular ligament, and to draw the scrotum slightly upwards, and a little to the right side, with his right hand, while he stands on the patient’s right side. Then the surgeon should seat himself in front of the perineum, having previously arranged with an assistant about having the instruments handed to him, or having already assorted them properly on a chair at his side; now it may be well to pass the forefinger of the left hand, oiled, into the rectum, to ascertain the size of the prostate (if that has not been done previously), and also the depth of this organ from the surface; next, having withdrawn his finger, he should trace the course of the ramus of the pubes and ischium on the left side, ascertain the position of the tuberosity of the latter bone on each side, and having scanned the whole surface, should proceed to use the knife (fig. 455), holding it as he would a scalpel or bistoury, as
LITHOTOMY.

725

exhibited in figures on pages 2 and 3, but with the hand and instrument more horizontal and directed to the perineum as represented at page 728. The point of the blade should be entered about one inch and three-fourths in front of the anus, about a line's breadth left of the raphe, pushed through the skin, and carried by a kind of sawing motion down the left side of the perineum, about an inch and a quarter beyond the anus, the middle of the incision being at equal distances from the latter part and the tuberosity, as indicated by the line on drawing 456; next, the blade should run along the surface

Fig. 456.

of the exposed fat and cellular tissue, and then the point of the forefinger of the left hand should be thrust into the wound a little in front of the anus, so as to penetrate between the accelerator urinae and the erector penis muscles,—the knife being applied to any part which offers resistance; when, with a little force to separate the tissues, the tip of the finger can be placed upon the membranous portion of the urethra, and the groove in the staff may be distinctly felt. The point of the blade, with the flat surfaces nearly horizontal, should now be carried along above the finger, made to perforate the urethra about three lines in front of the prostate, and then be slid along the groove until it has entered the bladder, having slit open the side of the urethra and notched the margin of the prostate in its course. If the stone is supposed to be of considerable magnitude, the blade should, in withdrawing it, be carried a little out of the groove, so as to increase the incision of the prostate. The forefinger of the left hand should next be slipped slowly into the bladder along the staff, in such a manner as to cause dilatation of the surrounding textures, and its point should be moved about in search of the stone, which being found, should be retained in a position near the neck of the viscus; then the assistant should be desired to remove the staff, and the surgeon should introduce the forceps (fig. 457) along the upper surface of the finger, slowly withdrawing the latter as the former makes progress: their
entrance will be denoted by a gush of urine, at which instant the blades should be separated, when on gently approximating them the stone will in all probability be felt enclosed. If it is not, the process may be repeated, if the water still flows, but should the bladder now be empty, the closed blades should be quietly moved about the bladder until the stone is touched, and at this time in opening and closing them great care should be taken to avoid any injury to the bladder. To make sure that the membrane has not been grasped, it is well to move the forceps a little before commencing extraction, when, if all is right, the process should be effected by a slow zigzag movement in a direction towards the floor, and with a slight pulling force, should this be required, as is most likely if the stone be large. Extraction being effected, the operation is completed. It may be well, however, in case of other concretions being present, to examine the interior of the bladder, with the point of the finger, with a common sound, or with such an instrument as is represented here (fig. 458), which is technically called a searcher; if others are present, they must be removed also; then the patient being unbound, should be carried to bed, desired to lie principally on his back, although he may occasionally be permitted to rest on either side, and the future treatment must be conducted according to circumstances.

Each stage of the operation and each instrument requires some separate consideration. It is recommended that the staff should be introduced as the first step,—chiefly because it can be more easily passed before the patient is bound, and also because it is satisfactory to touch the stone before going further. Unless the calculus be large and palpable, and this has been well ascertained before, the surgeon should never cut into the bladder without feeling the concretion when the patient is on the operating table. The staff usually permits him...
to do so; but as it is not of a convenient shape for making a minute search of the bladder, should that be required, it will be necessary to withdraw it, and pass a common short curved sound, which will probably be most conveniently used when the patient lies in the ordinary position for this process. In general the staff suffices for all the sounding which may be required at this particular time; therefore it is unnecessary to pass the regular sound at first; but as the former may possibly not suffice, and as it is possible also that the stone may not be detected even with the most careful examination, and as consequently the surgeon would not be justified in proceeding further, it is always best, in my opinion, to pass the staff before tying up the patient. This latter circumstance may to some appear of less consequence than I seem to attach to it,—indeed, in my own practice I have not always attended to it; but the staff is not in every instance introduced so readily as may be imagined; and in case of difficulty, as the attitude of the patient when his hands and feet are tied together might be supposed unfavourable,—as I believe it is in some,—the surgeon would regret having him thus bound;—besides, there is nothing more likely to ruffle the temper of an inexperienced operator than meeting unexpectedly a difficulty in this the beginning, and perhaps most simple step in the proceeding, and therefore he should avoid throwing annoyance in his own way, however petty it may appear to those familiar with such matters.

Before commencing the incisions, the operator should satisfy himself that the point of the staff has not slipped out of the bladder, which it is apt to do unless the assistant who holds it is careful; when assured on this subject, he should place it in the attitude in which he wishes it held afterwards, and then give it finally in charge to the assistant. It has been the custom with some to cause the convexity of the instrument to project in the left side of the perineum, but this seems unnecessary. It is not unusual even under chloroform, for the urine to escape between the staff and the urethra, particularly if the staff does not fill the diameter of this tube. This should be prevented by an assistant grasping the penis between the fingers and thumb. The groove in the staff is often erroneously made so long that it is above the glans penis, even when the point of the instrument is in the bladder. The urine is very likely to run off by this channel, and I therefore caution the young lithotomist to see that the instrument is not thus faulty, for I think it of consequence that there should be urine in the bladder during the operation, both when the knife is introduced and the finger and forceps are used as described on the preceding page.

The length of the external incision in the adult should be about three inches: but if the patient is fat, the perineum deep, and the stone large, it should be made longer,—at both ends, but especially in front. It has been a customary recommendation to have the external wound as far behind the anus as in front, but I believe that the lower part of the incision is seldom of much advantage, unless, indeed, the stone be very large; but even in such an instance it will be found that the skin towards the scrotum is more put on the stretch during
extraction than that behind: besides, an incision which is begun an inch and three-quarters or two inches in front of the anus, when the scrotum is held up in the manner recommended, will not appear so high after the parts are allowed to resume a more natural position. The skin alone should be divided in front, and between the tuberosity and the anus the blade may be carried deeper, although there is less occasion for this in general than some have supposed. The young surgeon is often told to cut freely here, because there is no important texture,—nothing but cellular tissue; but where the stone is not above an average size, there is actually no need of a wide gap in this situation.

A free division of the skin I consider a most important feature in the operation; but beyond this the application of the knife should, in my opinion, be extremely limited. The point of the finger may, in general, be thrust without much force into the space between the accelerator urinae and erector penis, provided the superficial fascia has been cut; it will then probably be arrested by the transversus perinei muscle, the lower part of the triangular ligament, and some of the fibres of the levator ani; but I believe the groove may be felt through these parts,—they may in a manner be squeezed up against it, and the puncture with the knife as it is carried onwards will usually suffice to admit the point of the finger, which, being accomplished, gives the operator the power of enlarging the wound to such an extent as to permit the introduction of the blades of the forceps. The dotted

Fig. 459.

lines, leading from the surface of the perineum in the accompanying drawing (fig. 459), will give an idea of the extent of the wound as far as the membranous portion of the urethra: the left forefinger is placed on that part as above recommended: the point of the knife is represented as being about to be carried onwards, and the dark line on the
prostate shows the probable extent of incision through the left lobe of that organ. It will be observed that a considerable portion of the gland remains intact, and that the line of incision is nearly parallel with, and a little below the attachment of the pelvic fascia. In all probability the transversus perinei muscle will tear under the finger, as will also such of the fibres of the levator ani, and of Wilson's, as may be interfered with: if, however, these or any other parts seem to resist the entrance of the finger, the edge of the blade should be turned against them; but as the amount of resistance cannot be well appreciated until the wound has been made into the bladder, and as it might be both troublesome and dangerous to use a sharp-pointed instrument any longer, a long, narrow, straight, probe-pointed bistoury, or a blade with a round point such as this (fig. 460) may be selected for the purpose. In some instances, where the prostate is very firm or the stone

![Fig. 460.](image)

is large, it may be desirable to make a freer opening in the gland than the line in the drawing indicates, and such a blade as that here exhibited will answer the purpose. It can be used before the stone is grasped by the forceps, or after, should the tissues not yield readily to moderate traction: if before, it may be carried a little further along the left lobe, or laid on the right one so as to divide it to a similar extent, and thus the operation may, in regard to this part of the wound, be considered bilateral. If the stone is between the forceps, the blade may still be put against one or other of these parts of the prostate; and, in so far as I can perceive, there should be no hesitation in cutting any part of the gland which seems to offer great resistance, with the exception perhaps of its under surface—where the position of the seminal ducts and other circumstances should deter the surgeon from using a cutting instrument. If it be possible to preserve a margin of the prostate at any part where it is cut, I think it of consequence to do so. There is thus, in my opinion, less chance of the bladder being torn during the extraction of a large stone, and therefore, probably, less subsequent risk to the patient from infiltration, inflammation, and deep-seated abscesses.

The cutting blades above recommended may be each set in a stout ebony handle, somewhat longer and thicker than that of the scalpel, or in clasp-handles. It is advisable to have the sharp-pointed one in this setting, as the operator can conveniently keep it in his vest-pocket until he is about to use it, and thus there will be no chance of the point being broken by an awkward assistant or an inquisitive looker-on.

I believe that in a large majority of cases the opening in the deep part of the perineum and neck of the bladder need not at first be larger than what the forefinger will stop, and as the latter follows the
course of the knife as soon as it is withdrawn, there will be as yet only a slight escape of urine; but when the forceps are used the fluid will gush out at once, at which time, as already stated, the stone may probably be seized, and thus further dilatation or the reappllication of the knife may be decided according to circumstances. For my own part I rarely apply the knife again, and whether the additional enlargement of this part of the wound be considered dilatation or laceration, I believe that the operation is a safer one than that by free incision into the tunics of the bladder beyond the prostate. A small deep incision and a somewhat forcible process of enlargement with the finger and forceps constituted features in the brilliant and dexterous practice of Mr. Liston. I have often thought that the particular method here referred to was in some respects like the celebrated and successful operation of Le Cat and his pupil Pajola, with the difference that Mr. Liston did with his left forefinger in entering the bladder, and with the forceps during extraction, what they did with a series of complicated instruments and manoeuvres. But from the time of Marianus Sanctorus (1524) to the present day there have been different opinions as to the propriety of limited or free incisions, and the best names are found on both sides of the question. The subject is too extensive for discussion in these pages, and I shall only add that, for my own part, I have, without cutting beyond the prostate, never experienced any remarkable difficulty in extracting stones weighing four ounces. In one instance I successfully removed a stone of nine ounces in weight through a comparatively limited incision, and with stones of an average bulk, so little force has been required that I have often thought the process of extraction more like lifting the stone off a smooth plain surface than bringing it through such a confessedly difficult passage as the ordinary wound in the lateral operation of lithotomy.

Perhaps the most dexterous part of the operation pertains to the use of the forceps. With such a narrow wound some care is required in slipping them towards the bladder, for otherwise their points might get between the prostate and rectum—indeed, even in using the forefinger there is danger, particularly in children, of passing in this direction. If a large opening be made in the neck of the bladder the urine must escape before the forceps be introduced; but if it be small, as has been recommended, the gush will not take place until they have entered the viscus, and if opened at this time there is every probability of the stone being carried between them by force of the current, as well as the natural contraction of the bladder which usually throws it towards the neck. If the stone is not grasped at the period referred to, the blades must be closed and moved about until they touch it; but now the bladder, having contracted, will prevent them being opened so readily as before. I have often found it of service to give the forceps a kind of shake, which seems to make the stone fall and settle down, as it were, in the most favourable position between the chops. In extracting, the movements should be slow, and the hand should, if necessary, be carried up and down, and from side to side, with such a degree of pulling as to cause the textures
to yield gradually. Occasionally it may be of service to introduce the point of the left forefinger to force the parts slightly backwards; and in all instances the prostate, and consequently the neck of the bladder, should be kept as much as possible in their natural position. In the different operations which I have witnessed, when there has been difficulty in extracting a stone of moderate size, or perhaps a little above the average, two circumstances have appeared to me as having had considerable influence in retarding the proceedings: first, the make of the forceps and next the mode of using them. If the blades be short between the hinge and the points, as they often are, their wedge-shape, when the stone is grasped, is too abrupt to cause that gradual dilatation which appears to me to be of so much consequence: besides being more apt to slip, they are thus brought against the interior of the neck of the bladder most abruptly, when the force exerted is more likely to bring the prostate against the rami of the pubes than to cause the expansion alluded to; moreover, the stone is now much less likely to come through than ever, as, in addition to the resistance of the gland, the interval between the bones is so narrow that it may be physically impossible for it to pass while the parts are thus situated. If, however, the blades be made of a length and shape in proportion to those exhibited at page 726, the above difficulty may, in some measure, be overcome: but still the extracting force must be applied gradually, in a direction towards the floor, and where the space between the bones is greatest. I believe that it is of some consequence also, to have the forceps of considerable length (from nine to ten inches for the adult), as the lever power may be of great importance when the stone is very large; and in all instances it is wise to have at hand a variety of different sizes, for occasionally a stone proves to be much larger than has been anticipated, and a full-sized instrument may then be of great service. The concavity of the jaws of the forceps is usually made rough with little metallic projections; but some prefer those lined with stout linen, which is sewed to them through apertures made on purpose, as may be seen in the drawing last alluded to. Sometimes it may be advantageous to have the forceps curved near the points, to reach more conveniently up behind the pubes or the lower part of the bladder; and in certain instances, such as when the stone is small or flat and difficult to seize, a scoop (fig. 461), will be more serviceable than the forceps. This instrument is used by passing it behind the stone, then fixing the latter against it with the point of the left forefinger, and thus withdrawing all three at the same time.

The principal hazards during the operation are, wound of the rectum or of some large blood-vessel. The former will be best avoided by keeping the knife, when in the deep part of the wound, chiefly above
the finger, which may also be used to depress the gut. Under the age of puberty there is seldom any annoyance from hemorrhage, but in the adult there may be both trouble and danger. The superficial perineal artery, or its transverse branch, is occasionally of such size, that when divided a ligature may be necessary:—it is usually so near the margin of the wound that it can be secured with facility. The artery of the bulb will seldom be cut, as the point of the knife should never be carried so high as this part; an anomalous branch (forming the dorsal artery of the penis) occasionally traverses the line of incision in the prostate, but such a circumstance is rarely met with, and when the scalpel is used (for it may be perceived that there is little difference between the blade represented at p. 724 and the last-named instrument, saving that the one for lithotomy is blunt towards the heel), its edge is not likely to encounter the common pudic. Perhaps the most troublesome hemorrhage may be from the veins around the neck of the bladder, which in those advanced in years are often of considerable size. If necessary, the opening in the skin might be enlarged, to permit the application of a ligature to a deep-seated artery, and it might even be possible to carry a curved needle round the pudic, were this deemed advisable: but in the generality of instances the bleeding ceases as soon as the patient's thighs are placed together,—for then the cut surfaces come more closely into apposition. Occasionally secondary hemorrhage occurs about the twelfth day after the operation, from a deep part of the wound; but I have never seen any serious mischief from it, and it has always ceased spontaneously in the examples which have come under my notice. Cold over the pubes may be resorted to,—but the most efficient means of all (especially when a ligature cannot be applied) is to use a tube like this (fig. 463), which, when introduced into the bladder, can be so surrounded by plugs of lint as to keep up very efficient pressure, while the urine is allowed to dribble away through the canal. A linen bag, open at both ends, about the length of the instrument, and two to three inches in diameter, is sometimes used in conjunction with this: one end of the bag is tied round the tube near the end which is to lie in the bladder, and the other is left open so that the lint for compression may be introduced between the tube and bag. A cautery bag has been ingeniously adapted to such a tube, by Mr. Matthews of Portugal-street, which, when filled with air or water, is intended to act in a similar manner. The tube is about six inches long and half an inch thick, and must be retained in its place by tapes, passed in front and behind the pelvis, fastened to a band or another tape round the loins. When withdrawn, at the end of four-and-twenty or eight-and-forty hours, the effused lymph on the cut surfaces will have closed the divided vessels. A tube of this
LITHOTOMY.

kind is of ancient date. It was strongly advised by Mr. Liston for the sake of carrying off the water for the first two days, and I believe that it is still in general use in Edinburgh for that purpose, although I am not aware that it was applied in that city before his time, or that it has been much used in any London hospital excepting University College. In the earlier years of my practice I used this instrument, but having had reason to doubt its supposed advantages, I laid it aside, and have treated nearly two hundred cases of lithotomy without any casualty which I could attribute to its absence.

As the urine must escape by the wound for the next ten or fifteen days, a piece of Macintosh cloth should be laid between the patient and the mattress; a folded blanket or sheet should also be placed under his breech, a sponge may be put in front of the wound, to absorb part of the urine, and care should be taken to keep the skin as dry as possible. Usually, from the swelling of the parts in the track of the incision, the urine passes freely by the urethra on the second or third day, but it soon again all escapes by the wound; then on the eighth, ninth, or tenth, it flows in part by the natural course, and in a few days more is entirely evacuated through this channel. The aperture in the perineum generally closes in about three weeks or a month, sometimes earlier, and occasionally later, a few drops of urine coming from time to time, for six weeks or more, through a small chink still unclosed.

The treatment after lithotomy, as regards diet, the state of the bowels, and the various evil consequences of the proceeding not particularly referred to above—such as infiltration, wound of the rectum, inflammation of the neck of the bladder, or of the peritoneum, &c. &c., should be conducted on the ordinary principles of surgery, which, it is presumed, must be known to any one who would undertake the operation.

Some years ago a proposal was made by Dr. Willis to extract the stone by dilating the neck of the bladder, after making an incision in the perineum and opening the membranous portion of the urethra, in imitation of an operation once performed by Sir Astley Cooper, at the suggestion of the Drs. Arnott, and partly also of the old method of Romanus and Marianus by the apparatus major; but it remains to be proved in how far the operation—to which Dr. Willis has given the name of Lithectasy, is to be preferred to the present method. A most intelligent friend, Mr. Thomas Elliot, of Carlisle, successfully extracted a stone in this manner on a young man of seventeen. Dr. Wright, of Malton, Yorkshire, also had a successful operation of the kind. In the summer of 1843 I treated a patient, aged sixty-four, by this proceeding, but the issue was fatal; though during the operation I had the good fortune of having the aid and advice of Dr. Willis himself. The case was published at length in The Lancet, vol. ii. 1843. In this operation I made an incision in the perineum, in the shape of an inverted Y thus (fig. 463), having the impression that a straight line in the course of the raphe, with diverging slips on each side of the anus, would permit of more ready expansion than any
other shape or direction of external wound; and I have occasionally, for similar reasons, performed lithotomy by such an opening in the skin. Professor Eve, of Nashville University, Tennessee, who performs the bilateral operation, has adopted this incision in preference to the semicircular one recommended by Dupuytren, and I fancy that a larger opening in the lower part of the pelvis could be made in this way, without danger to the rectum or other important parts, than by any other external wound.

Among the numerous authors on the subject of lithotomy, there is difficulty in selecting those most worthy of notice in such a work as this; and it is not deemed necessary to advert in any particular manner to the modifications which have been or are practised with regard to different steps in the proceedings. Of the method with the cutting gorget I have had little experience; and although I have seen the operation admirably executed with this instrument by the late Mr. Green at St. Thomas's Hospital, I cannot but express my concurrence with the prevailing feeling of the present day, that the scalpel or bistoury is the safest instrument for making the wound in the neck of the bladder. No author with whose works I am acquainted has so clearly pointed out the deplorable effects of the gorget as the late Mr. Crosse, and, in so far as I am myself able to form an opinion, the instrument might be altogether dispensed with among modern surgeons. The lithotome caché I have never seen used, and the bilateral operation, with the ingenious double-blade lithotome of Dupuytren, seems to have few practical admirers in this country. The only novelty which I think worthy of notice here, is the ingenious proceeding recommended by Dr. A. Buchanan, of Glasgow. Instead of the staff with the ordinary curve, he uses what he calls a rectangular one. The angle is about three inches from the point of the instrument, and is intended to project "prominently at the most posterior point of the perineum, while the short arm lies horizontally under the level of the bulb of the urethra, an assistant pressing the instrument firmly downwards to maintain it steadily in that position. The operation is then performed by a single stroke of a double-edged lithotomy knife, which, as it penetrates in the mesial line towards the bladder, passes through the middle of the upper half of the sphincter ani, the membranous part of the urethra and the apex of the prostate, and as it is withdrawn divides the body of the gland, the levator ani, the skin of the perineum:—the direction of the knife as it comes out being first horizontally outward and then backward." For a particular description of the instrument and operation, I must refer to the Monthly Journal of Medical Science for 1848. Dr. Buchanan, in a communication which he favoured me with on the subject, and from which I have, at his own request, introduced the foregoing extract, states that thirty-five patients had been cut in this way in the Glasgow Infirmary, thirty-two of whom recovered. Some notice of this operation has been taken in London by the late Mr. Avery, Mr.
LITHOTOMY.

Hutchinson, and others, and it seems to me to deserve more attention than has heretofore been given to it.

Mr. G. Allarton has proposed a modification of lithotomy, which, in some respects, resembles the ancient proceeding by the apparatus major, the incision in the pericicum over the bulb being much the same, and the rapid distension or dilatation of the neck of the bladder being also somewhat analogous. The late Mr. Teale, of Leeds, paid considerable attention to this operation, and practised it frequently; so have many others, but it does not seem likely to supersede the old lateral, as above described. What I have seen has not impressed me with the idea that it has superior advantages.

Some years ago I tried on the living body a variety of incisions. Besides the inverted Y referred to on the preceding page, I varied the incision for the lateral operation by beginning at the top on the right side of the raphé, crossing that line to the left side. I also gave trial to the semilunar incision in front of the anus as made for the old operation of cutting on the gripe, and published a paper on the subject in The Lancet for 4th January, 1868, with some illustrative cases, but the method described does not seem to have found favour with those who perform lithotomy; and upon the whole the lateral operation of Cheselden still holds sway over the surgical mind of Britain.

Through the polite attention of the late Mr. Key, I had an opportunity of witnessing with what ease and dexterity he performed the operation on a straight staff in a way peculiar to himself, and of which he has published an account, but partly from custom, and partly because I think that, in the present state of our knowledge of the means of extracting a stone from the bladder by lithotomy, the proceeding of Frère Jaques, which was in a manner rendered perfect by Cheselden, has not been excelled, whether as regards facility of execution or safety to the patient, I give his method the preference. The highest averages of success (one death in five, in six, in seven, and in eight) have been attained in this way, by Cheselden himself, and by many who have imitated his movements, and among whom I may enumerate, as perhaps the most successful, Messrs. Martineau and Dalrymple, of Norwich, Mr. Crichton, of Dundee, and Mr. Liston, whose operations I often witnessed in former years with admiration.

MESSRS. J. & A. CHURCHILL'S
Publications
in
MEDICINE
AND THE VARIOUS BRANCHES OF
NATURAL SCIENCE.

"It would be unjust to conclude this notice without saying a few words in favour of Mr. Churchill, from whom the profession is receiving, it may be truly said, the most beautiful series of Illustrated Medical Works which has ever been published."—Lancet.

"All the publications of Mr. Churchill are prepared with so much taste and neatness, that it is superfluous to speak of them in terms of commendation."—Edinburgh Medical and Surgical Journal.

"No one is more distinguished for the elegance and recherché style of his publications than Mr. Churchill."—Provincial Medical Journal.

"The name of Churchill has long been a guarantee for the excellence of illustrated works, and it would be superfluous to repeat the admiration that we have several times expressed in this respect, of the spirit with which this firm engages in these costly but valuable series."—Medical Press and Circular.

"The typography, illustrations, and getting up are, in all Mr. Churchill's publications, most beautiful."—Monthly Journal of Medical Science.

"Mr. Churchill's illustrated works are among the best that emanate from the Medical Press."—Medical Times.

"We have before called the attention of both students and practitioners to the great advantage which Mr. Churchill has conferred on the profession, in the issue, at such a moderate cost, of works so highly creditable in point of artistic execution and scientific merit."—Dublin Quarterly Journal.
Messrs. J. & A. CHURCHILL are the Publishers of the following Periodicals, offering to Authors a wide extent of Literary Announcement, and a Medium of Advertisement, addressed to all Classes of the Profession.

THE BRITISH AND FOREIGN MEDICO-CHIRURGICAL REVIEW, AND QUARTERLY JOURNAL OF PRACTICAL MEDICINE AND SURGERY.
Price Six Shillings. No. C.

THE QUARTERLY JOURNAL OF MICROSCOPICAL SCIENCE,

THE JOURNAL OF MENTAL SCIENCE.
By authority of the Medico-Psychological Association.
Edited by Henry Maedsley, M.D., and John Sibbald, M.D.
Published Quarterly, price 3s. 6d. New Series. No. XLVII.

ARCHIVES OF MEDICINE:
A Record of Practical Observations and Anatomical and Chemical Researches, connected with the Investigation and Treatment of Disease. Edited by Dr. Lionel S. Beale, F.R.S. No. XVII, 3d.

THE MEDICAL DIRECTORY.
Published Annually. 8vo. 10s. 6d.

THE YEAR-BOOK OF PHARMACY,
Published Annually. 8vo, 7s. 6d.

THE ROYAL LONDON OPHTHALMIC HOSPITAL REPORTS, AND JOURNAL OF OPHTHALMIC MEDICINE AND SURGERY.
Vol. VII., Part 3, 2s. 6d.

THE MEDICAL TIMES & GAZETTE.
Published Weekly, price Sixpence. Annual Subscription, £1. 6s., and regularly forwarded to all parts of the Kingdom, post free, for £1. 8s.

THE PHARMACEUTICAL JOURNAL, AND TRANSACTIONS OF THE PHARMACEUTICAL SOCIETY.
Published Weekly, price Fourpence.
* May also be had in Monthly Parts.

THE BRITISH JOURNAL OF DENTAL SCIENCE.
Published Monthly, price One Shilling.
No. CXCVI.

THE HALF-YEARLY ABSTRACT OF THE MEDICAL SCIENCES.
Being a Digest of British and Continental Medicine, and of the Progress of Medicine and the Collateral Sciences. Edited by W. Domett Stone, M.D., F.R.C.S. (Exam.). Post 8vo., 6s. 6d. Vols. 1. to LV.

Messrs. CHURCHILL have concluded a special arrangement with Messrs. LINDSAY & BLAKISTON, of PHILADELPHIA, in accordance with which that Firm will act as their Agents for the United States of America, either keeping in Stock most of Messrs. CHURCHILL's Books, or reprinting them on Terms advantageous to Authors. Many of the Works in this Catalogue may therefore be easily obtained in America.

ON DISEASES OF THE LIVER.
Illustrated with Coloured Plates and Engravings on Wood. Third Edition. 8vo., 16s.

GEORGE BUDD, M.D., F.R.C.P., F.R.S.

ON THE ORGANIC DISEASES AND FUNCTIONAL DISORDERS OF THE STOMACH. 8vo., 9s.

G. W. CALLENDER, F.R.C.S.

FEMORAL RUPTURE: Anatomy of the Parts concerned. With Plates. 8vo., 4s.

JOHN M. CAMPLIN, M.D., F.L.S.

ON DIABETES, AND ITS SUCCESSFUL TREATMENT.
Third Edition, by Dr. Glover. Fcap. 8vo., 3s. 6d.

W. B. CARPENTER, M.D., F.R.S.

PRINCIPLES OF HUMAN PHYSIOLOGY. With nearly 300 Illustrations on Steel and Wood. Seventh Edition. Edited by Mr. Henry Power. 8vo., 28s.

A MANUAL OF PHYSIOLOGY. With 252 Illustrations on Steel and Wood. Fourth Edition. Fcap. 8vo., 12s. 6d.

THE MICROSCOPE AND ITS REVELATIONS. With more than 400 Engravings on Steel and Wood. Fourth Edition. Fcap. 8vo., 12s. 6d.

T. K. CHAMBERS, M.D., F.R.C.P.

LECTURES, CHIEFLY CLINICAL. Fourth Edition. 8vo., 14s.

THE INDIGESTIONS OR DISEASES OF THE DIGESTIVE ORGANS FUNCTIONALLY TREATED. Second Edition. 8vo., 10s. 6d.

SOME OF THE EFFECTS OF THE CLIMATE OF ITALY. Crown 8vo., 4s. 6d.

H. T. CHAPMAN, F.R.C.S.

JOHN CHAPMAN, M.D., M.R.C.P.

THE MEDICAL INSTITUTIONS OF THE UNITED KINGDOM; a History exemplifying the Evils of Over-Legislation. 8vo., 3s. 6d.
MESSRS. J. & A. CHURCHILL'S PUBLICATIONS.

PYE HENRY CHAVASSE, F.R.C.S.

I. ADVICE TO A MOTHER ON THE MANAGEMENT OF HER CHILDREN. Tenth Edition. Foolscap 8vo., 2s. 6d.

II. COUNSEL TO A MOTHER: being a Continuation and the Completion of "Advice to a Mother." Second Edition. Fcap. 8vo., 2s. 6d.

III. ADVICE TO A WIFE ON THE MANAGEMENT OF HER OWN HEALTH. With an Introductory Chapter, especially addressed to a Young Wife. Ninth Edition. Fcap. 8vo., 2s. 6d.

F. LE GROS CLARK, F.R.C.S.

I. LECTURES ON THE PRINCIPLES OF SURGICAL DIAGNOSIS, ESPECIALLY IN RELATION TO SHOCK AND VISCERAL LESIONS, delivered at the Royal College of Surgeons. 8vo., 10s. 6d.

JOHN CLAY, M.R.C.S.

T. SPENCER COBBOLD, M.D., F.R.S.

WORMS: a Series of Lectures delivered at the Middlesex Hospital on Practical Helminthology. Post 8vo., 5s.

OAKLEY COLES.

DEFORMITIES OF THE MOUTH; CONGENITAL and ACQUIRED; their Mechanical Treatment. With Coloured Plates. Second Edition, 8vo., 5s. 6d.

MAURICE H. COLLIS, M.D.DUB., F.R.C.S.I.

THE DIAGNOSIS AND TREATMENT OF CANCER AND THE TUMOURS ANALOGOUS TO IT. With coloured Plates. 8vo., 14s.

A. J. COOLEY.

W. WHITE COOPER, F.R.C.S.

I. ON WOUNDS AND INJURIES OF THE EYE. Illustrated by 17 Coloured Figures and 41 Woodcuts. 3vo., 12s.

II. ON NEAR SIGHT, AGED SIGHT, IMPAIRED VISION, AND THE MEANS OF ASSISTING SIGHT. With 31 Illustrations on Wood. Second Edition. Fcap. 8vo., 7s. 6d.

R. P. COTTON, M.D., F.R.C.P.

PHthisis and the Stethoscope; or, the Physical Signs of Consumption. Fourth Edition. Foolscap 8vo., 3s. 6d.

WALTER J. COULSON, F.R.C.S.

A TREATISE ON SYPHILIS. 8vo., 10s.

STONE IN THE BLADDER: Its Prevention, Early Symptoms, and Treatment by Lithotripsy. 8vo., 6s.

T. B. CURLING, F.R.C.S., F.R.S.

OBSERVATIONS ON DISEASES OF THE RECTUM. Third Edition. 8vo., 7s. 6d.

THOMAS CUTLER, M.D.

WILLIAM DALE, M.D., LONDON.

A COMPENDIUM OF PRACTICAL MEDICINE AND MORBID ANATOMY. With Plates, 12mo., 7s.

DONALD DALRYMPLE, M.P., M.R.C.P.

THE CLIMATE OF EGYPT: METEOROLOGICAL AND MEDICAL OBSERVATIONS, with Practical Hints for Invalid Travellers. Post 8vo., 4s.

JOHN DALRYMPLE, F.R.C.S., F.R.S.

PATHOLOGY OF THE HUMAN EYE. Complete in Nine Fasciculi: imperial 4to., 20s. each; half-bound morocco, gilt tops, 91. 15s.

FRED. DAVIES, M.D., F.R.C.S.

HENRY DAY, M.D., M.R.C.P.

CLINICAL HISTORIES; with Comments. 8vo., 7s. 6d.

CAMPBELL DE MORGAN, F.R.S., F.R.C.S.

THE ORIGIN OF CANCER considered with Reference to the Treatment of the Disease. Crown 8vo., 3s. 6d.

HORACE DOBELL, M.D.

DEMONSTRATIONS OF DISEASES IN THE CHEST, AND THEIR PHYSICAL DIAGNOSIS. With Coloured Plates. 8vo., 12s. 6d.

LECTURES ON THE GERMS AND VESTIGES OF DISEASE, and on the Prevention of the Invasion and Fatality of Disease by Periodical Examinations. 8vo., 6s. 6d.

LECTURES ON WINTER COUGH (CATARRH, BRONCHITIS, EMPHYSEMA, ASTHMA); with an Appendix on some Principles of Diet in Disease. Second Edition, with Coloured Plates. 8vo., 8s. 6d.

LECTURES ON THE TRUE FIRST STAGE OF CONSUMPTION. Crown 8vo., 3s. 6d.

A MANUAL FOR HOSPITAL NURSES AND OTHERS ENGAGED IN ATTENDING ON THE SICK. Crown 8vo., 2s. 6d.

NEURALGIA: its various Forms, Pathology, and Treatment. The Jacksonian Prize Essay for 1850. 8vo., 10s. 6d.

THE SURGEON'S VADE-MECUM; with numerous Engravings on Wood. Tenth Edition. Foolscap 8vo., 12s. 6d.

ROBERT DRUITT, F.R.C.S.

ON CEREBRIA AND OTHER DISEASES OF THE BRAIN. 8vo., 6s.

MEDICINE, DISEASE, AND DEATH: being an Enquiry into the Progress of Medicine as a Practical Art. 8vo., 3s. 6d.

EDWARD ELLIS, M.D.

SIR JAMES EYRE, M.D.

THE STOMACH AND ITS DIFFICULTIES. Sixth Edition, by Mr. Beale. Pep. 8vo., 2s. 6d.

J. FAYRER, M.D., F.R.C.S., C.S.I.

CLINICAL SURGERY IN INDIA, With Engravings. 8vo., 16s.

THE THANATOPHILIA OF INDIA; being a Description of the Venemous Snakes of the Indian Peninsula; with an Account of the Influence of their Poison on Life, and a Series of Experiments. With 31 Plates (20 Coloured), Folio, £7. 7s.
MESSRS. J. & A. CHURCHILL’S PUBLICATIONS.

SAMUEL FENWICK, M.D., F.R.C.P.

THE MORBID STATES OF THE STOMACH AND DUODENUM, AND THEIR RELATIONS TO THE DISEASES OF OTHER ORGANS. With 10 Plates. 8vo., 12s.

THE STUDENT'S GUIDE TO MEDICAL DIAGNOSIS. Second Edition. With 60 Engravings. Fcap. 8vo., 6s. 6d.

SIR WILLIAM FERGUSSON, BART., F.R.C.S., F.R.S.

A SYSTEM OF PRACTICAL SURGERY; with 463 Illustrations on Wood. Fifth Edition. 8vo., 21s.

LECTURES ON THE PROGRESS OF ANATOMY AND SURGERY DURING THE PRESENT CENTURY. With numerous Engravings. 8vo., 10s. 6d.

W. H. FLOWER, F.R.C.S., F.R.S.

DIAGRAMS OF THE NERVES OF THE HUMAN BODY, exhibiting their Origin, Divisions, and Connexions, with their Distribution to the various Regions of the Cutaneous Surface, and to all the Muscles. Second Edition, containing Six Plates, Royal 4to.

BALTHAZAR W. FOSTER, M.D.

METHOD AND MEDICINE: an Essay on the Past, Present, and Future of Medicine. 8vo., 2s. 6d.

G. FOWNES, PH.D., F.R.S.

CHEMISTRY, AS EXEMPLIFYING THE WISDOM AND BENEFICENCE OF GOD. Second Edition. Fcap. 8vo., 4s. 6d.

INTRODUCTION TO QUALITATIVE ANALYSIS. Post 8vo., 2s.

D. J. T. FRANCIS, M.D., F.R.C.P.

CHANGE OF CLIMATE; considered as a Remedy in Dyspeptic, Pulmonary, and other Chronic Affections; with an Account of the most Eligible Places of Residence for Invalids, at different Seasons of the Year. Post 8vo., 8s. 6d.

W. H. FULLER, M.D., F.R.C.P.

ON DISEASES OF THE LUNGS AND AIR PASSAGES. Second Edition. 8vo., 12s. 6d.

ON DISEASES OF THE HEART AND GREAT VESSELS.

ON RHEUMATISM, RHEUMATIC GOUT, AND SCIATICA: their Pathology, Symptoms, and Treatment. Third Edition. 8vo., 12s. 6d.
MESSRS. J. & A. CHURCHILL'S PUBLICATIONS.

REMIGIUS FRESENIUS.

A SYSTEM OF INSTRUCTION IN CHEMICAL ANALYSIS
Edited by ARTHUR VACHER.
QUALITATIVE. Eighth Edition. 8vo., 12s. 6d.
QUANTITATIVE. Fifth Edition. 8vo., 12s. 6d.

ROBERT GALLOWAY.
I.
THE FIRST STEP IN CHEMISTRY. With numerous Engravings.
Fourth Edition. Fcap. 8vo., 6s. 6d.
A KEY TO THE EXERCISES. 2s. 6d.

II.
THE SECOND STEP IN CHEMISTRY; or, the Student's Guide to
the Higher Branches of the Science. With Engravings. 8vo., 10s.

III.
A MANUAL OF QUALITATIVE ANALYSIS. Fifth Edition.
With Engravings. Post 8vo., 8s. 6d.

IV.
CHEMICAL TABLES. On Five Large Sheets, for School and Lecture
Rooms. Second Edition. 4s. 6d.

J. SAMPSO GAMGEE, M.R.C.S.

ON THE TREATMENT OF FRACTURES OF THE LIMBS.
With Plates. 8vo., 10s. 6d.

F. J. GANT, F.R.C.S.

I.
THE PRINCIPLES OF SURGERY: Clinical, Medical, and Opera-
tive. With Engravings. 8vo., 18s.

II.
THE SCIENCE AND PRACTICE OF SURGERY: a complete
System and Textbook. With 470 Engravings. 8vo., £1. 4s.

III.
THE IRRITABLE BLADDER: its Causes and Treatment. Third

C. B. GARRETT, M.D.

IRRITATIVE DYSPEPSIA AND ITS IMPORTANT CON-
NECTION with IRRITATIVE CONGESTION of the WINDPIPE, and with
the Origin and Progress of Consumption. Crown 8vo., 2s. 6d.

GEORGE GASKOIN, SURGEON.

THE MEDICAL WORKS OF FRANCISCO LOPEZ DE VILLA-
LOBOS, the celebrated Court Physician of Spain; containing the Poem on the
Pestiferous Bubas; Dialogues on Medicine (15th and 16th centuries); &c. With
Biography and Commentary. Post 8vo., 10s. 6d.

JOHN GAY, F.R.C.S.

ON VARICOSE DISEASE OF THE LOWER EXTREMITIES.
LettSOMIAN LECTURES. With Plates. 8vo., 5s.

SIR DUNCAN GIBB, BART., M.D.

THE LARYNGOSCOPE IN DISEASES OF THE THROAT,
MESSRS. J. & A. CHURCHILL’S PUBLICATIONS.

A Manual of the Laws Affecting Medical Men. With a Chapter on Medical Etiquette by Dr. A. Carpenter. 8vo, 14s.

Benjamin Godfrey, M.D., F.R.A.S.
Diseases of Hair: a popular Treatise upon the Affections of the Hair System. Fcap. 8vo, 3s. 6d.

C. A. Gordon M.D., C.B.
Army Hygiene. 8vo, 20s.

Michael C. Grabham, M.D., M.R.C.P.
The Climate and Resources of Madeira, as regarding chiefly the Necessities of Consumption and the Welfare of Invalids. With Map and Engravings. Crown 8vo, 5s.

R. J. Graves, M.D., F.R.S.
Studies in Physiology and Medicine. Edited by Dr. Stokes. With Portrait and Memoir. 8vo, 14s.

J. Reay Greene, M.D.
Tables of Zoology, indicating the Tribes, Sub-Orders, Orders, and Higher Groups of the Animal Kingdom. Three Large Sheets.

T. Griffiths.
Chemistry of the Four Seasons—Spring, Summer, Autumn, Winter. Illustrated with Engravings on Wood. Second Edition. Foolscape 8vo, 7s. 6d.

W. A. Guy, M.B., F.R.S., and John Harley, M.D., F.R.C.P.

Guy’s Hospital Reports. Third Series. Vol. XVII, 8vo. 7s. 6d.

S. O. Habershon, M.D., F.R.C.P.

On the Injurious Effects of Mercury in the Treatment of Disease. Post 8vo, 3s. 6d.

On Diseases of the Liver. Lettsomian Lectures for 1872. Post 8vo, 3s. 6d.

O. Radclyffe Hall, F.R.C.P.
Torquay in its Medical Aspect as a Resort for Pulmonary Invalids. Post 8vo, 5s.
REV. T. F. HARDWICH.

A MANUAL OF PHOTOGRAPHIC CHEMISTRY. With Engravings. Seventh Edition. Foolscap 8vo., 7s. 6d.

GEORGE HARLEY, M.D., F.R.S., F.R.C.P.

LECTURES ON THE URINE AND ITS DERANGEMENTS, with the Application of Physiological Chemistry to the Diagnosis and Treatment of Constitutional as well as Local Diseases. Post 8vo., 9s.

J. BOWER HARRISON, M.D., M.R.C.P.

I. LETTERS TO A YOUNG PRACTITIONER ON THE DISEASES OF CHILDREN. Foolscap 8vo., 3s.

II. ON THE CONTAMINATION OF WATER BY THE POISON OF LEAD, and its Effects on the Human Body. Foolscap 8vo., 3s. 6d.

GEORGE HARTWIG, M.D.

I. ON SEA BATHING AND SEA AIR. Second Edition. Fcap. 8vo., 2s. 6d.

II. ON THE PHYSICAL EDUCATION OF CHILDREN. Fcap. 8vo., 2s. 6d.

ALFRED HAVILAND, M.R.C.S.

CLIMATE, WEATHER, AND DISEASE; being a Sketch of the Opinions of the most celebrated Ancient and Modern Writers with regard to the Influence of Climate and Weather in producing Disease. With Four coloured Engravings. 8vo., 7s.

W. HAYCOCK, M.R.C.V.S.

HORSES; HOW THEY OUGHT TO BE SHOD: being a plain and practical Treatise on the Principles and Practice of the Farrier’s Art. With 14 Plates. 7s. 6d.

F. W. HEADLAND, M.D., F.R.C.P.

II. A MEDICAL HANDBOOK; comprehending such Information on Medical and Sanitary Subjects as is desirable in Educated Persons. Second Thousand. Foolscap 8vo., 5s.

J. N. HEALE, M.D., M.R.C.P.

I. A TREATISE ON THE PHYSIOLOGICAL ANATOMY OF THE LUNGS. With Engravings. 8vo., 8s.

II. A TREATISE ON VITAL CAUSES. 8vo., 9s.
CHRISTOPHER HEATH, F.R.C.S.

II. A MANUAL OF MINOR SURGERY AND BANDAGING, FOR THE USE OF HOUSE-SURGEONS, DRESSERS, AND JUNIOR PRACTITIONERS. With 74 Engravings. Fourth Edition. Fcap. 8vo., 5s. 6d.

JOHN HIGGINBOTTOM, F.R.S., F.R.C.S.E.

JOHN D. HILL, F.R.C.S.

AN ANALYSIS OF 140 CASES OF ORGANIC STRICTURE OF THE URETHRA, of which 120 were submitted to HOLT'S OPERATION, and 20 to PERINEAL SECTION. 8vo., 3s.

WILLIAM HINDS, M.D.

THE HARMONY'S OF PHYSICAL SCIENCE IN RELATION TO THE HIGHER SENTIMENTS; with Observations on Medical Studies, and on the Moral and Scientific Relations of Medical Life. Post 8vo., 4s.

RICHARD HODGES, M.D.

THE NATURE, PATHOLOGY, AND TREATMENT OF PUBERAL CONVULSIONS. Crown 8vo., 3s.

DECIMUS HODGSON, M.D.

THE PROSTATE GLAND, AND ITS ENLARGEMENT IN OLD AGE. With 12 Plates. Royal 8vo., 6s.

LUTHER HOLDEN, F.R.C.S.

I. HUMAN OSTEEOLOGY: with Plates, showing the Attachments of the Muscles. Fourth Edition. 8vo., 16s.

BARNARD HOLT, F.R.C.S.

MESSRS. J. & A. CHURCHILL’S PUBLICATIONS.

C. HOLTHOUSE, F.R.C.S.
ON HERNIAL AND OTHER TUMOURS OF THE GROIN and its NEIGHBOURHOOD; with some Practical Remarks on the Radical Cure of Ruptures. 8vo., 6s. 6d.

P. HOOD, M.D.
A TREATISE ON GOUT, RHEUMATISM, AND THE ALLIED AFFECTIONS. Crown 8vo., 10s. 6d.

THE SUCCESSFUL TREATMENT OF SCARLET FEVER; also, OBSERVATIONS ON THE PATHOLOGY AND TREATMENT OF CROWING INSPIRATIONS OF INFANTS. Post 8vo., 5s.

JOHN HORSLEY.
A CATECHISM OF CHEMICAL PHILOSOPHY; being a Familiar Exposition of the Principles of Chemistry and Physics. With Engravings on Wood. Designed for the Use of Schools and Private Teachers. Post 8vo., 6s. 6d.

JAMES A. HORTON, M.D.
PHYSICAL AND MEDICAL CLIMATE AND METEOROLOGY OF THE WEST COAST OF AFRICA. 8vo., 10s.

LUKE HOWARD, F.R.S.
ESSAY ON THE MODIFICATIONS OF CLOUDS. Third Edition, by W. D. and E. Howard. With 6 Lithographic Plates, from Pictures by Kenyon. 4to., 10s. 6d.

A. HAMILTON HOWE, M.D.
A THEORETICAL INQUIRY INTO THE PHYSICAL CAUSE OF EPIDEMIC DISEASES. Accompanied with Tables. 8vo. 7s.

C. W. HUFELAND.
THE ART OF PROLONGING LIFE. Second Edition. Edited by ERASMUS WILSON, F.R.S. Foolscape 8vo., 2s. 6d.

W. CURTIS HUGMAN, F.R.C.S.
ON HIP-JOINT DISEASE; with reference especially to Treatment by Mechanical Means for the Relief of Contraction and Deformity of the Affected Limb. With Plates. Re-issue, enlarged. 8vo., 3s. 6d.

G. Y. HUNTER, M.R.C.S.
BODY AND MIND: the Nervous System and its Derangements. Fcap. 8vo., 3s. 6d.
A CLINICAL MEMOIR ON CERTAIN DISEASES OF THE EYE AND EAR, CONSEQUENT ON INHERITED SYPHILIS; with an appended Chapter of Commentaries on the Transmission of Syphilis from Parent to Offspring, and its more remote Consequences. With Plates and Woodcuts, 8vo., 9s.

T. H. HUXLEY, LL.D., F.R.S.

MANUAL OF THE ANATOMY OF VERTEBRATED ANIMALS.
With 110 Engravings. Fcap. 8vo., 12s.

INTRODUCTION TO THE CLASSIFICATION OF ANIMALS.
With Engravings. 8vo., 6s.

THOMAS INMAN, M.D., M.R.C.P.

JAMES JAGO, M.D.OXON., A.B.CANTAB.

ENTOPTICS, WITH ITS USES IN PHYSIOLOGY AND MEDICINE. With 54 Engravings. Crown 8vo., 5s.

H. BENOE JONES, M.D., M.R.C.P.

LECTURES ON SOME OF THE APPLICATIONS OF CHEMISTRY AND MECHANICS TO PATHOLOGY AND THERAPEUTICS. 8vo., 12s.

C. HANDFIELD JONES, M.B., F.R.C.P., F.R.S.

A MANUAL OF PATHOLOGICAL ANATOMY. Illustrated with numerous Engravings on Wood. Foolscape 8vo., 12s. 6d.
JAMES JONES, M.D., M.R.C.P.
ON THE USE OF PERCHLORIDE OF IRON AND OTHER CHALYBEATE SALTS IN THE TREATMENT OF CONSUMPTION. Crown 8vo., 3s. 6d.

T. WHARTON JONES, F.R.C.S., F.R.S.
II. THE WISDOM AND BENEFICENCE OF THE ALMIGHTY, AS DISPLAYED IN THE SENSE OF VISION. Actonian Prize Essay. With Illustrations on Steel and Wood. Foolscap 8vo., 4s. 6d.
IV. A CATECHISM OF THE MEDICINE AND SURGERY OF THE EYE AND EAR. For the Clinical Use of Hospital Students. Fcap. 8vo., 2s. 6d.
V. A CATECHISM OF THE PHYSIOLOGY AND PHILOSOPHY OF BODY, SENSE, AND MIND. For Use in Schools and Colleges. Fcap. 8vo., 2s. 6d.

FURNEAUX JORDAN, F.R.C.S.
THE TREATMENT OF SURGICAL INFLAMMATIONS BY A NEW METHOD, WHICH GREATLY SHORTENS THEIR DURATION. With Plates. 8vo., 7s. 6d.

U. J. KAY-SHUTTLEWORTH, M.P.

GEORGE KENNION, M.D., F.R.C.P.

DR. LAENNEC.
A MANUAL OF AUSCULTATION AND PERCUSSION. Translated and Edited by J. B. SHARPE, M.R.C.S. Fcap. 8vo., 3s.

SIR WM. LAWRENCE, BART., F.R.S.
I. LECTURES ON SURGERY. 8vo., 16s.
II. A TREATISE ON RUPTURES. The Fifth Edition, considerably enlarged. 8vo., 16s.
ARTHUR LEARED, M.D., F.R.C.P.

IMPERFECT DIGESTION: ITS CAUSES AND TREATMENT.  
Fifth Edition. Foolscap 8vo., 4s. 6d.

HENRY LEE, F.R.C.S.

Lectures on Suppurative Fever, Diseases of the Veins, Haemorrhoidal Tumours, Diseases 
of the Rectum, Syphilis, Gonorrhœal Ophthalmia, &c. 8vo., 10s. each vol.

ROBERT LEE, M.D., F.R.C.P., F.R.S.

I. CONSULTATIONS IN MIDWIFERY. Foolscap 8vo., 4s. 6d.
II. A TREATISE ON THE SPECULUM; with Three Hundred Cases. 8vo., 4s. 6d.
III. CLINICAL REPORTS OF OVARIAN AND UTERINE DIS- 
EASES, with Commentaries. Foolscap 8vo., 6s. 6d.

WM. LEISHMAN, M.D., F.F.P.S.

THE MECHANISM OF PARTURITION: An Essay, Historical and 
Critical. With Engravings. 8vo., 5s.

F. HARWOOD LESCHER.

THE ELEMENTS OF PHARMACY. 8vo., 7s. 6d.

DR. LIEBREICH.

ATLAS OF OPHTHALMOSCOPY: representing the Normal and Patho-
logical Conditions of the Fundus Oculi as seen with the Ophthalmoscope. Composed of 
12 Chromo-lithographic Plates (containing 59 Figures), accompanied by an Explanatory 
Text, translated into English by H. Rosborough SWANSEY, M.B. Dub. Second Edition, 
Enlarged and Revised. 4to., £1. 10s.

ROBERT LISTON, F.R.S.

PRACTICAL SURGERY. Fourth Edition. 8vo., 22s.

D. D. LOGAN, M.D., M.R.C.P., LOND.

ON OBSTINATE DISEASES OF THE SKIN. Fcap. 8vo., 2s. 6d.

LONDON HOSPITAL.

CLINICAL LECTURES AND REPORTS BY THE MEDICAL 
AND SURGICAL STAFF. With Illustrations. Vols. I. to IV. 8vo., 7s. 6d.
LONDON MEDICAL SOCIETY OF OBSERVATION.

WHAT TO OBSERVE AT THE BED-SIDE, AND AFTER DEATH. Published by Authority. Second Edition. Foolscape 8vo., 4s. 6d.

HENRY LOWNDES, M.R.C.S.

AN ESSAY ON THE MAINTENANCE OF HEALTH. Fcap. 8vo., 2s. 6d.

WILLIAM MACCORMAC, F.R.C.S., M.R.I.A.

NOTES AND RECOLLECTIONS OF AN AMBULANCE SURGEON; being an Account of Work done under the Red Cross during the Campaign of 1870. With 8 Plates. 8vo., 7s. 6d.

MORELL MACKENZIE, M.D. LOND., M.R.C.P.

GROWTHS IN THE LARYNX, with Reports and an Analysis of 100 consecutive Cases treated by the Author since the Invention of the Laryngoscope. With Coloured Plates. 8vo., 12s. 6d.

A. C. MACLEOD, M.R.C.P. LOND.

ACHOLIC DISEASES; comprising Jaundice, Diarrhoea, Dysentery, and Cholera. Post 8vo., 5s. 6d.

GEORGE H. B. MACLEOD, M.D., F.R.C.S. EDIN.

THROAT HOSPITAL PHARMACOPOEIA, containing upwards of 150 Formulae. Fcap. 8vo., 2s. 6d.

A. C. MACLEOD, M.R.C.P. LOND.

ACCOLIC DISEASES; comprising Jaundice, Diarrhoea, Dysentery, and Cholera. Post 8vo., 5s. 6d.

GEORGE H. B. MACLEOD, M.D., F.R.C.S. EDIN.

NOTES ON THE SURGERY OF THE CRIMEAN WAR; with REMARKS on GUN-SHOT WOUNDS. 8vo., 10s. 6d.

WM. MACLEOD, M.D., F.R.C.P. EDIN.

THE THEORY OF THE TREATMENT OF DISEASE ADOPTED AT BEN RHYDDING. Fcap. 8vo., 2s. 6d.

JOSEPH MACLISE, F.R.C.S.

N. C. MACNAMARA.

A TREATISE ON ASIATIC CHOLERA; with Maps. 8vo., 16s.

WM. MARCET, M.D., F.R.C.P., F.R.S.

MESSRS. J. & A. CHURCHILL'S PUBLICATIONS.

J. MACPHERSON, M.D.

Cholera in its Home; with a Sketch of the Pathology and Treatment of the Disease. Crown 8vo., 5s.

W. O. MARKHAM, M.D., F.R.C.P.

skoda on Auscultation and percussion. Post 8vo., 6s.

alexander marsden, M.D., F.R.C.S.

A New and Successful Mode of Treating Certain Forms of Cancer; to which is prefixed a Practical and Systematic Description of all the Varieties of this Disease. With Coloured Plates. 8vo., 6s. 6d.

J. H. MARTIN.

A Manual of Microscopic Mounting. With upwards of 100 Engravings on Stone and Wood. 8vo., 7s. 6d.

Sir ranald martin, C.B., F.R.C.S., F.R.S.

Influence of Tropical Climates in Producing the Acute Endemic Diseases of Europeans; including Practical Observations on the Chronic Sequelæ under the Influences of the Climate of Europe. Second Edition, much enlarged. 8vo., 20s.

P. MARTYN, M.D.LOND.

Hooping-Cough; Its Pathology and Treatment. With Engravings. 8vo., 2s. 6d.

C. F. MAUNDER, F.R.C.S.

Operative Surgery. With 158 Engravings. Post 8vo., 6s.

R. G. MAYNE, M.D., LL.D.

An Expository Lexicon of the Terms, Ancient and Modern, in Medical and General Science. 8vo., £2. 10s.

A Medical Vocabulary; or, an Explanation of all Names, Synonyms, Terms, and Phrases used in Medicine and the relative branches of Medical Science. Third Edition. Fcap. 8vo., 8s. 6d.

EDWARD MERYON, M.D., F.R.C.P.

On the Functions of the Sympathetic System of Nerves as a Physiological Basis for a Rational System of Therapeutics. 8vo., 3s. 6d.

Pathological and Practical Researches on the Various Forms of Paralysis. 8vo., 6s.

W. J. MOORE, M.D.

Health in the Tropics; or, Sanitary Art applied to Europeans in India. 8vo., 9s.

A Manual of the Diseases of India. Fcap. 8vo., 5s.
MESSRS. J. & A. CHURCHILL'S PUBLICATIONS.

JAMES MORRIS, M.D. LOND.

GERMINAL MATTER AND THE CONTACT THEORY:

II.

IRRITABILITY: Popular and Practical Sketches of Common Morbid States and Conditions bordering on Disease; with Hints for Management, Alleviation, and Cure. Crown 8vo., 4s. 6d.

G. J. MULDER.

THE CHEMISTRY OF WINE. Edited by H. Bence Jones, M.D., F.R.S. Fcap. 8vo., 6s.

W. MURRAY, M.D., F.R.C.P.

EMOTIONAL DISORDERS OF THE SYMPATHETIC SYSTEM OF NERVES. Crown 8vo., 3s. 6d.

W. B. MUSHET, M.B., F.R.C.P.

ON APOPLEXY, AND ALLIED AFFECTIONS OF THE BRAIN. 8vo., 7s.

ARTHUR B. R. MYERS, M.R.C.S.

ON THE ETIOLOGY AND PREVALENCE OF DISEASES of the HEART among SOLDIERS. With Diagrams. The "Alexander" Prize Essay. 8vo., 4s.

GEORGE NAYLER, F.R.C.S.

ON THE DISEASES OF THE SKIN. With Plates. 8vo., 10s. 6d.

J. BIRKBECK NEVINS, M.D.

THE PRESCRIBER'S ANALYSIS OF THE BRITISH PHARMACOPEIA of 1867. 32mo., 3s. 6d.

PATRICK NICOL, M.B.

A TRANSLATION OF DR. DILLNBERGER'S HANDY-BOOK of the TREATMENT of WOMEN'S and CHILDREN'S DISEASES according to the VIENNA MEDICAL SCHOOL. With Prescriptions. Fcap. 8vo., 5s.

H. M. NOAD, PH.D., F.R.S.

SELBY NORTON, M.D.

INFANTILE DISEASES: their Causes, Prevention, and Treatment, showing by what Means the present Mortality may be greatly reduced. Fcap. 8vo., 2s. 6d.

FRANCIS OPPERT, M.D., M.R.C.P.

I.

HOSPITALS, INFIRMARIES, AND DISPENSARIES; their Construction, Interior Arrangement, and Management, with Descriptions of existing Institutions. With 68 Engravings. Royal 8vo., 10s. 6d.

II.

VISCEAL AND HEREDITARY SYPHILIS. 8vo., 5s.
NOTES ON COMPARATIVE ANATOMY: A Syllabus of a Course of Lectures delivered at St. Thomas's Hospital. Crown 8vo 5s.

THE MODERN TREATMENT OF SYPHILITIC DISEASES, both Primary and Secondary; comprising the Treatment of Constitutional and Confirmed Syphilis, by a safe and successful Method. Fifth Edition, 8vo., 10s. 6d.

A MANUAL OF PRACTICAL HYGIENE; intended especially for the Medical Officers of the Army. With Plates and Woodcuts. 3rd Edition, 8vo., 16s.

THE URINE: ITS COMPOSITION IN HEALTH AND DISEASE, AND UNDER THE ACTION OF REMEDIES. 8vo., 12s.

THE ANTIDOTAL TREATMENT AND PREVENTION OF THE EPIDEMIC CHOLERA. Third Edition. 8vo., 7s. 6d.

EGYPT AND THE NILE AS A WINTER RESORT FOR PULMONARY AND OTHER INVALIDS. Fcap. 8vo., 3s.

DIGESTION: ITS DISORDERS AND THEIR TREATMENT. Second Edition. 8vo., 8s. 6d.

ON SOME OF THE CAUSES AND EFFECTS OF VALVULAR DISEASE OF THE HEART. With Engravings. 8vo., 5s.

SELECTA E PRÆSCRIPTIS. Fifteenth Edition. 24mo., 5s.
HYGIENE; or, Health as Depending upon the Conditions of the Atmosphere, Food and Drinks, Motion and Rest, Sleep and Wakefulness, Secretions, Excretions, and Retentions, Mental Emotions, Clothing, Bathing, &c. Vol. I. 8vo., 9s.

ON HAY ASTHMA, AND THE AFFECTION TERMED HAY FEVER. Fcap. 8vo., 2s. 6d.

ILLUSTRATIONS OF SOME OF THE PRINCIPAL DISEASES OF THE EYE: With an Account of their Symptoms, Pathology and Treatment. Twelve Coloured Plates. 8vo., 20s.

THE GENEALOGY OF CREATION, newly Translated from the Unpointed Hebrew Text of the Book of Genesis, showing the General Scientific Accuracy of the Cosmogony of Moses and the Philosophy of Creation. 8vo., 14s.

ON ORBITAL MOTION: The Outlines of a System of Physical Astronomy. With Diagrams. 8vo., 7s. 6d.

THE PRESCRIBER'S PHARMACOPEIA; the Medicines arranged in Classes according to their Action, with their Composition and Doses. By a Practising Physician. Fifth Edition. 32mo., cloth, 2s. 6d.; roan tuck (for the pocket), 3s. 6d.

AIDS DURING LABOUR, including the Administration of Chloroform, the Management of Placenta and Post-partum Haemorrhage. Fcap. 8vo., 4s. 6d.

AN ESSAY ON EXCISION OF THE KNEE-JOINT. With Coloured Plates. With Memoir of the Author and Notes by Henry Smith, F.R.C.S. Royal 8vo., 14s.

W. O. PRIESTLEY, M.D., F.R.O.P.
LECTURES ON THE DEVELOPMENT OF THE GRAVID UTERUS. 8vo., 5s. 6d.

F. H. RAMSBothAM, M.D., F.R.O.P.
THE PRINCIPLES AND PRACTICE OF OBSTETRIC MEDICINE AND SURGERY. Illustrated with One Hundred and Twenty Plates on Steel and Wood; forming one thick handsome volume. Fifth Edition. 8vo., 22s.

THOMAS READE, M.B.T.C.D., L.R.C.S.I.
SYPHILITIC AFFECTIONS OF THE NERVOUS SYSTEM, AND A CASE OF SYMMETRICAL MUSCULAR ATROPHY; with other Contributions to the Pathology of the Spinal Marrow. Post 8vo., 5s.

DU BOIS REYMOND.
ANIMAL ELECTRICITY; Edited by H. Bence Jones, M.D., F.R.S. With Fifty Engravings on Wood. Foolscap 8vo., 6s.

J. RUSSELL REYNOLDS, M.D.LOND., F.R.C.P., F.R.S.
I. EPILEPSY: ITS SYMPTOMS, TREATMENT, AND RELATION TO OTHER CHRONIC CONVULSIVE DISEASES. 8vo., 10s.

II. THE DIAGNOSIS OF DISEASES OF THE BRAIN, SPINAL CORD, AND THEIR APPENDAGES. 8vo., 8s.

III. LECTURES ON THE CLINICAL USES OF ELECTRICITY delivered at University College Hospital. Post 8vo., 3s. 6d.

B. W. RICHARDSON, M.D., F.R.O.P., F.R.S.
I. ON THE CAUSE OF THE COAGULATION OF THE BLOOD, Being the Astley Cooper Prize Essay for 1856. With a Practical Appendix. 8vo., 16s.

II. DISCOURSES ON PRACTICAL PHYSIC. 8vo., 5s.
WILLIAM ROBERTS, M.D., F.R.C.P.

AN ESSAY ON WASTING PALSY; being a Systematic Treatise on the Disease hitherto described as ATROPHIE MUSCULAIRE PROGRESSIVE. With Four Plates. 8vo., 5s.

C. H. F. ROUTH, D.M., M.R.C.P.

INFANT FEEDING, AND ITS INFLUENCE ON LIFE; Or, the Causes and Prevention of Infant Mortality. Second Edition. Fcap. 8vo., 6s.

W. H. ROBERTSON, M.D., F.R.C.P.

I. THE NATURE AND TREATMENT OF GOUT. 8vo., 10s. 6d.

JAMES ROGERS, M.D.

ON THE PRESENT STATE OF THERAPEUTICS. With some Suggestions for placing it on a more scientific basis. 8vo., 6s. 6d.

JAMES ROSS, M.D.

THE GRAFT THEORY OF DISEASE, being an application of Mr. Darwin's Theory of Pangenesis to the explanation of the Phenomena of the Zymotic Diseases. 8vo., 10s.

G. R. ROWE, M.D.

NERVOUS DISEASES, LIVER AND STOMACH COMPLAINTS, LOW SPIRITS, INDIGESTION, GOUT, ASTHMA, AND DISORDERS PRODUCED BY TROPICAL CLIMATES. With Cases. Sixteenth Edition. Fcap. 8vo., 2s. 6d.

J. F. ROYLE, M.D., F.R.S. AND F. W. HEADLAND, M.D., F.R.C.P.

A MANUAL OF MATERIA MEDICA AND THERAPEUTICS. With numerous Engravings on Wood. Fifth Edition. Fcap. 8vo., 12s. 6d.

J. T. SABBEN, M.D. AND J. H. BALFOUR BROWNE.

HANDBOOK OF LAW AND LUNACY; or, the Medical Practitioners Complete Guide in all Matters relating to Lunacy Practice. 8vo. 5s.

ST. GEORGE'S HOSPITAL REPORTS. Vols. I to V. 8vo., 7s. 6d.

ST. THOMAS'S HOSPITAL REPORTS. Vols. I. and II., New Series, 8vo., 8s.

H. HYDE SALTER, M.D., F.R.C.P., F.R.S.
